Preface

The Annual Symposium on Combinatorial Pattern Matching is an international forum for research in combinatorial pattern matching and related applications. It addresses issues of searching and matching strings and more complicated patterns such as trees, regular expressions, graphs, point sets, and arrays. The goal is to derive combinatorial properties of such structures and to exploit these properties in order to achieve more efficient algorithms for the corresponding computational problems. The meeting deals with problems in bioinformatics and computational biology, coding and data compression, combinatorics on words, data mining, information retrieval, natural language processing, pattern discovery, string algorithms, string processing in databases, symbolic computing, and text searching and indexing.

This volume contains the papers presented at the 28th Annual Symposium on Combinatorial Pattern Matching (CPM 2017) held on July 4-6, 2017 in Warsaw, Poland.

The conference programme included 28 contributed papers and three invited talks by Artur Jeż (University of Wrocław, Poland), Giovanni Manzini (University of Eastern Piedmont and IIT-CNR, Italy), and Marcin Mucha (University of Warsaw, Poland). Contributions of the invited lectures are also included in this volume.

The contributed papers were selected out of 49 submissions, corresponding to an acceptance ratio of about 57%. Each submission received at least three reviews. We thank the members of the Programme Committee and all the additional external reviewers that are listed below for their hard and invaluable work that resulted in an excellent scientific programme.

The Annual Symposium on Combinatorial Pattern Matching started in 1990, and has since then taken place every year. Previous CPM meetings were held in Paris, London (UK), Tucson, Padova, Asilomar, Helsinki, Laguna Beach, Aarhus, Piscataway, Warwick, Montreal, Jerusalem, Fukuoka, Morelia, Istanbul, Jeju Island, Barcelone, London (Ontario, Canada), Pisa, Lille, New York, Palermo, Helsinki, Bad Herrenalb, Moscow, Ischia, and Tel Aviv. From the 3rd to the 26th meeting, all proceedings were published in the LNCS (Lecture Notes in Computer Science) series. The 27th meeting in 2016 was the first to have its proceedings appear in the LIPIcs (Leibniz International Proceedings in Informatics) series, as volume 54.

The whole submission and review process was carried out with the help of the EasyChair conference system. We thank the CPM Steering Committee for supporting Warsaw as the site for CPM 2017 and for their advice and help in different issues. We thank Tomasz Kociumaka and Tomasz Waleń from the University of Warsaw for their extensive involvement in the organisation of the conference and Hanna Bargiel and Monika Goszczycka from Global Congress, Poland for the local arrangements. We would like to thank the Warsaw Center of Mathematics and Computer Science for providing generous financial support to the conference.

Wheeler Graphs: Variations on a Theme by Burrows and Wheeler

Giovanni Manzini

Computer Science Institute, DiSIT, University of Eastern Piedmont, Alessandria, Italy; and
IIT-CNR, Pisa, Italy
giovanni.manzini@uniupo.it

Abstract

The famous Burrows-Wheeler Transform was originally defined for single strings but variations have been developed for sets of strings, labelled trees, de Bruijn graphs, alignments, etc. In this talk we propose a unifying view that includes many of these variations and that we hope will simplify the search for more.

Somewhat surprisingly we get our unifying view by considering the Nondeterministic Finite Automata related to different pattern-matching problems. We show that the state graphs associated with these automata have common properties that we summarize with the concept of a Wheeler graph. Using the notion of a Wheeler graph, we show that it is possible to process strings efficiently even if the automaton is nondeterministic. In addition, we show that Wheeler graphs can be compactly represented and traversed using up to three arrays with additional data structures supporting efficient rank and select operations. It turns out that these arrays coincide with, or are substantially equivalent to, the output of many Burrows-Wheeler Transform variants described in the literature.

This is joint work with Travis Gagie and Jouni Sirén.

---

On many occasions Mike Burrows stated that the original idea of the transformation is due to David Wheeler. We therefore decided to name this graph class after this pioneer of computer science.
Recompression of SLPs

Artur Jeż

Institute of Computer Science, University of Wrocław, Wrocław, Poland

Abstract
In this talk I will survey the recompression technique in case of SLPs. The technique is based on applying simple compression operations (replacement of pairs of two different letters by a new letter and replacement of maximal repetition of a letter by a new symbol) to strings represented by SLPs. To this end we modify the SLPs, so that performing such compression operations on SLPs is possible. For instance, when we want to replace \( ab \) in the string and SLP has a production \( X \rightarrow aY \) and the string generated by \( Y \) is \( bw \), then we alter the rule of \( Y \) so that it generates \( w \) and replace \( Y \) with \( bY \) in all rules. In this way the rule becomes \( X \rightarrow abY \) and so \( ab \) can be replaced, similar operations are defined for the right sides of the nonterminals. As a result, we are interested mostly in the SLP representation rather than the string itself and its combinatorial properties. What we need to control, though, is the size of the SLP. With appropriate choices of substrings to be compressed it can be shown that it stays linear.

The proposed method turned out to be surprisingly efficient and applicable in various scenarios: for instance it can be used to test the equality of SLPs in time \( O(n \log N) \), where \( n \) is the size of the SLP and \( N \) the length of the generated string; on the other hand it can be used to approximate the smallest SLP for a given string, with the approximation ratio \( O(\log(n/g)) \), where \( n \) is the length of the string and \( g \) the size of the smallest SLP for this string, matching the best known bounds.

Shortest Superstring

Marcin Mucha

University of Warsaw, Warsaw, Poland

Abstract

In the Shortest Superstring problem (SS) one has to find a shortest string $s$ containing given strings $s_1, \ldots, s_n$ as substrings. The problem is NP-hard, so a natural question is that of its approximability.

One natural approach to approximately solving SS is the following GREEDY heuristic: repeatedly merge two strings with the largest overlap until only a single string is left. This heuristic is conjectured to be a $2$-approximation, but even after 30 years since the conjecture has been posed, we are still very far from proving it. The situation is better for non-greedy approximation algorithms, where several approaches yielding $2.5$-approximation (and better) are known.

In this talk, we will survey the main results in the area, focusing on the fundamental ideas and intuitions.

Document Listing on Repetitive Collections with Guaranteed Performance

Gonzalo Navarro

Center for Biotechnology and Bioengineering, Department of Computer Science, University of Chile, Santiago, Chile
gnavarro@dcc.uchile.cl

Abstract
We consider document listing on string collections, that is, finding in which strings a given pattern appears. In particular, we focus on repetitive collections: a collection of size $N$ over alphabet $[1,\sigma]$ is composed of $D$ copies of a string of size $n$, and $s$ single-character edits are applied on the copies. We introduce the first document listing index with size $\widetilde{O}(n+s)$, precisely $O((n \log \sigma + s \log^2 N) \log D)$ bits, and with useful worst-case time guarantees: Given a pattern of length $m$, the index reports the $ndoc$ strings where it appears in time $O(m^2 + m \log N (\log D + \log^\epsilon N) \cdot ndoc)$, for any constant $\epsilon > 0$.

1 Introduction

Document retrieval on general string collections is an area that has recently attracted attention [24]. On the one hand, it is a natural generalization of the basic Information Retrieval tasks carried out on search engines [1, 4], many of which are also useful on Far East languages, collections of genomes, code repositories, multimedia streams, etc. It also enables phrase queries on natural language texts. On the other hand, it raises a number of algorithmic challenges that are not easily addressed with classical pattern matching approaches.

In this paper we focus on one of the simplest document retrieval problems, document listing [22]. Let $D$ be a collection of $D$ documents of total length $N$. We want to build an index on $D$ such that, later, given a search pattern $P$ of length $m$, we report the identifiers of all the $ndoc$ documents where $P$ appears. Given that $P$ may occur $occ \gg ndoc$ times in $D$, resorting to pattern matching, that is, finding all the $occ$ occurrences and then listing the distinct documents where they appear, can be utterly inefficient. Optimal $O(m + ndoc)$ time document listing solutions appeared only in 2002 [22], although they use too much space.

There are also more recent statistically compressed indices [29, 15] with a small time penalty.

In particular, we are interested in highly repetitive string collections [23], which are formed by a few distinct documents and a number of near-copies of those. Such collections arise, for example, when sequencing the genomes of thousands of individuals of a few species, when managing versioned collections of documents like Wikipedia, and in versioned software repositories. Although many of the fastest-growing datasets are indeed repetitive, this is

* Supported in part by Fondecyt grant 1-170048 and Basal Funds FB0001, Conicyt, Chile.
an underdeveloped area: most succinct indices for string collections are based on statistical compression, and these fail to exploit repetitiveness [19].

1.1 Our contribution

There are few document listing indices that profit from repetitiveness. A simple model to analyze them is as follows [21, 12, 23]: Assume there is a single document of size \( n \) on alphabet \([1, \sigma]\), and \( D - 1 \) copies of it, on which \( s \) single-character edits are arbitrarily distributed, forming a collection of size \( N \approx nD \). This models, for example, collections of genomes and their single-point mutations. The gold standard to measure space usage on repetitive collections is the size of the Lempel-Ziv parsing [20]. If we parse the concatenation of the strings in such a repetitive collection, we obtain at most \( z = n/\lg \sigma \cdot n + O(s) \ll N \) phrases. Therefore, while a statistical compressor would require basically \( N \lg \sigma \) bits if the base document is incompressible [19], we can aim to reach as little as \( O((n \lg \sigma + s \lg N) \cdot \lg \sigma) \) bits by exploiting repetitiveness via Lempel-Ziv compression.

This might be too optimistic for an index, however, as there is no known way to extract substrings efficiently from Lempel-Ziv compressed text. Instead, grammar compression allows extracting any text symbol in logarithmic time using \( O(r \lg N) \) bits, where \( r \) is the size of the grammar [3, 31]. It is possible to obtain a grammar of size \( r = O(z \lg(N/z)) \) [5, 16], which using standard methods [28] can be tweaked to \( r = n/\lg \sigma \cdot N + s \lg N \) under our repetitiveness model. Thus the space we might aim at for indexing is \( O((n \lg \sigma + s \lg^2 N) \cdot \lg \sigma) \) bits.

Although they perform reasonably well in practice, none of the preceding structures for document listing on repetitive collections [8, 12] offer good worst-case time guarantees combined with space guarantees that are appropriate for repetitive collections, that is, growing with \( n + s \) rather than with \( N \). Those offering search times of the form \( O(\text{poly}(m, \lg N) \cdot ndoc) \) require space of the form \( O(N/\text{poly}(\lg N)) \). In this paper we present the first index offering good guarantees in space and time. Namely, our index

1. uses \( O((n \lg \sigma + s \lg^2 N) \cdot \lg D) \) bits of space, and
2. performs document listing in time \( O(m^2 + m \lg N (\lg D + \lg \epsilon N) \cdot ndoc) \), for any constant \( \epsilon > 0 \).

That is, our index is an \( O(\lg D) \) space factor away from what could be hoped from a grammar-based index. We actually build on a grammar-based document listing index [8] that stores lists of the documents where each nonterminal appears, and strengthen it by rearranging the nonterminals in different orders, following a wavelet tree [13] deployment that guarantees that only \( O(m \lg r) \) ranges of lists have to be merged at query time. We do not store the lists themselves in various orders, but just succinct range minimum query (RMQ) data structures [11] that allow implementing document listing on ranges of lists [29]. Those RMQ structures are further compressed because their underlying data has long increasing runs, so the structures are reduced with techniques analogous to those developed for the ILCP data structure [12]. The space reduction brings new issues, however, because we cannot afford storing the underlying RMQ sequences. These problems are circumvented with a new, tailored, technique to extract the distinct documents in a range.

2 Related work

The first optimal-time and linear-space solution to document listing is due to Muthukrishnan [22], who solves the problem in \( O(m + ndoc) \) time using an index of \( O(N \lg N) \) bits of space. Later solutions [29, 15] improved the space to essentially the statistical entropy of \( D \), at the
price of multiplying the times by low-order polylogs of $N$ (e.g., $O(m + \lg N \cdot \text{ndoc})$ time with $O(N)$ bits on top of the entropy). As said, however, statistical entropy does not capture repetitiveness well [19], and thus these solutions are not satisfactory in repetitive collections.

There has been a good deal of work on pattern matching indices for repetitive string collections, building on various principles (see [26, Sec 13.2]). However, there has been little work on document retrieval structures for repetitive string collections.

One precedent is Claude and Munro’s index based on grammar compression [8]. It builds on a grammar-based pattern-matching index [10] and adds an inverted index that explicitly indicates the documents where each nonterminal appears; this inverted index is also grammar-compressed. To obtain the answer, an unbounded number of those lists of documents must be merged. No relevant worst-case time or space guarantees are offered.

Another precedent is ILCP [12], where it is shown that the longest common prefix array (LCP) of repetitive collections has long increasing runs. Then an index of size bounded by the runs in the suffix array [21] and in the LCP array performs document listing in $O(n \lg N + s \lg^2 N)$ bits. A more serious problem is that, to obtain $\text{lookup}(N)$ time per document, a suffix array sampling of $O(N \lg N / \text{lookup}(N))$ bits must be stored.

The last previous work is PDL [12], which stores inverted lists at sampled nodes in the suffix tree of $D$, and then grammar-compresses the set of inverted lists. For a sampling step $b$, it requires $O((N/b) \lg N)$ bits plus the (unbounded) space of the inverted lists. Searches that lead to the sampled nodes have their answers precomputed, whereas the others cover a suffix array range of size $O(b)$ and are solved by brute force in time $O(b \cdot \text{lookup}(N))$. Again, the suffix array sampling of $O(N \lg N / \text{lookup}(N))$ bits is necessary.

3 Basic Concepts

3.1 Listing the different elements in a range

Let $A[1, t]$ be an array of integers in $[1, D]$. Muthukrishnan [22] gives a structure that, given a range $[i, j]$, lists all the $\text{ndoc}$ distinct elements in $A[i, j]$ in time $O(\text{ndoc})$. He defines an array $C[1, t]$ storing in $C[k]$ the largest position $l < k$ where $A[l] = A[k]$, or $C[k] = 0$ if no such position exists. Note that the leftmost positions of the distinct elements in $A[i, j]$ are exactly those $k$ where $C[k] < i$. He then stores a data structure supporting range-minimum queries (RMQs) on $C$, $\text{rmq}_C(i, j) = \min_{i \leq k \leq j} C[k]$ [11]. Given a range $[i, j]$, he computes $k = \text{rmq}_C(i, j)$. If $C[k] < i$, then he reports $A[k]$ and continues recursively on $A[i, k - 1]$ and $A[k + 1, j]$. Whenever it turns out that $C[k] \geq i$ for an interval $[x, y]$, there are no leftmost occurrences of $A[i, j]$ within $A[x, y]$, so this interval can be abandoned. It is easy to see that the algorithm takes $O(\text{ndoc})$ time and uses $O(t \lg t)$ bits of space; the RMQ structure uses just $2t + o(t)$ bits and answers queries in constant time [11].

Furthermore, the RMQ structure does not even access $C$, so we can replace $C$ by a bitvector $V[1, D]$ to mark which elements have been reported. We set $V$ initially to all zeros and replace the test $C[k] < i$ by $V[A[k]] = 0$, that is, the value $A[k]$ has not yet been reported (these tests are equivalent only if we recurse left and then right in the interval [24]). If so, we report $A[k]$ and set $V[A[k]] \leftarrow 1$. Overall, we need only $O(t + D)$ bits of space on top of $A$, and still run in $O(\text{ndoc})$ time [29] ($V$ can be reset to zeros by rerunning the query or through lazy initialization). Hon et al. [15] further reduce the extra space to $o(t)$ bits, yet increasing the time, via sampling the array $C$.
3.2 Wavelet trees

A wavelet tree [13] is a sequence representation that supports, in particular, two-dimensional orthogonal range queries [6, 25]. Let \((1, y_1), (2, y_2), \ldots, (r, y_r)\) be a sequence of points with \(y_i \in [1, r]\), and let \(S = y_1y_2\ldots y_r\) be the \(y\) coordinates in order. The wavelet tree is a perfectly balanced binary tree where each node handles a range of \(y\) values. The root handles \([1, r]\). If a node handles \([a, b]\) then its left child handles \([a, \mu]\) and its right child handles \([\mu + 1, b]\), with \(\mu = \lfloor (a + b)/2 \rfloor\). The leaves handle individual \(y\) values. If a node handles range \([a, b]\), then it represents the subsequence \(S_{a,b}\) of \(y\) coordinates that belong to \([a, b]\). Thus at each level the strings \(S_{a,b}\) form a permutation of \(S\). What is stored for each such node is a bitvector \(B_{a,b}\) so that \(B_{a,b}[i] = 0\) iff \(S_{a,b} \leq \mu\), that is, if that value is handled in the left child of the node. Those bitvectors are provided with support for rank and select queries: \(\text{rank}_c(B, i)\) is the number of occurrences of bit \(v\) in \(B[1, i]\), whereas \(\text{select}_c(B, j)\) is the position of the \(j\)th occurrence of bit \(v\) in \(B\). The wavelet tree has height \(\lg r\), and its total space requirement for all the bitvectors \(B_{a,b}\) is \(r \lg r\) bits. The extra structures for rank and select add \(O(r \lg r)\) further bits and support the queries in constant time [7]. With the wavelet tree one can recover any \(y_i\) value by tracking it down from the root to a leaf, but let us describe a more general procedure.

Let \([x_1, x_2] \times [y_1, y_2]\) be a query range. The number of points that fall in the range can be counted in \(O(\lg r)\) time as follows. We start at the root with the range \(S[x_1, x_2] = S_{1,r}[x_1, x_2]\). Then we project the range both left and right, towards \(S_{1,\mu}[\text{rank}_0(B_{1,r}, x_1 - 1), 1, \text{rank}_0(B_{1,r}, x_2)]\) and \(S_{\mu+1,r}[\text{rank}_1(B_{1,r}, x_1 - 1) + 1, \text{rank}_1(B_{1,r}, x_2)]\), respectively, with \(\mu = \lfloor (r + 1)/2 \rfloor\). If some of the ranges is empty, we stop the recursion on that node. If the interval \([a, b]\) handled by a node is disjoint with \([y_1, y_2]\), we also stop. If the interval \([a, b]\) is included in \([y_1, y_2]\), then all the points in the \(x\) range qualify, and we simply sum the length of the range to the count. Otherwise, we keep splitting the ranges recursively. It is well known that the range \([y_1, y_2]\) is covered by \(O(\lg r)\) wavelet tree nodes, and that we traverse \(O(\lg r)\) nodes to reach them. If we also want to report all the corresponding \(y\) values, then instead of counting the points found, we track each one individually towards its leaf, in \(O(\lg r)\) time. At the leaves, the \(y\) values are sorted, so in particular if they are a permutation of \([1, r]\), we know that the \(i\)th left-to-right leaf is the value \(y = i\). Thus, extracting the \(\text{nooc}\) results takes time \(O((1 + \text{nooc}) \lg r)\).

3.3 Range minimum queries on arrays with runs

Let \(A[1,t]\) be an array that can be cut into \(\rho\) runs of nondecreasing values. Then it is possible to solve RMQs in \(O(\lg \lg t)\) time plus \(O(1)\) accesses to \(A\) using \(O(\rho \lg(t/\rho))\) bits. The idea is that the possible minima (breaking ties in favor of the leftmost) in \(A[i, j]\) are either \(A[i]\) or the positions where runs start in the range. Then, we can use a sparse bitvector \(M[1,t]\) marking with \(M[k] = 1\) the run heads. We also define an array \(A'[1,\rho]\), so that if \(M[k] = 1\) then \(A'[\text{rank}_1(M, k)] = A[k]\). We do not store \(A'\), but just an RMQ structure on it. Hence, the minimum of the run heads in \(A[i, j]\) can be found by computing the range of run heads involved, \(i' = \text{rank}_1(M, i - 1) + 1\) and \(j' = \text{rank}_1(M, j)\), then finding the smallest value among them in \(A'\) with \(k' = \text{RMQ}_{A'}(i', j')\), and mapping it back to \(A\) with \(k = \text{select}_1(M, k')\). Finally, the RMQ answer is either \(A[i]\) or \(A[k]\), so we access \(A\) twice to compare them.

This idea was used by Gagie et al. [12, Sec 3.2] for runs of equal values, but it works verbatim for runs of nondecreasing values. They show how to store \(M\) in \(\rho \lg(t/\rho) + O(\rho)\) bits so that it solves rank in \(O(\lg \lg t)\) time and select in \(O(1)\) time, by enriching a sparse bitvector representation [27]. This dominates the space and time of the whole structure.
The idea was used even before by Barbay et al. [2, Thm. 2], for runs of nondecreasing values. They represented \( M \) using \( \rho \lg(t/\rho) + O(\rho) + o(t) \) bits so that the \( O(\lg \lg t) \) time becomes \( O(1) \), but we are not be able to afford the \( o(t) \) extra bits in this paper.

### 3.4 Grammar compression

Let \( T[1, N] \) be a sequence of symbols over alphabet \( [1, \sigma] \). Grammar compressing \( T \) means finding a context-free grammar that generates \( T \) and only \( T \). The grammar can then be used as a substitute for \( T \), which provides good compression when \( T \) is repetitive. We are interested, for simplicity, in grammars in Chomsky normal form, where the rules are of the form \( A \rightarrow BC \) or \( A \rightarrow a \), where \( A, B, \) and \( C \) are nonterminals and \( a \in [1, \sigma] \) is a terminal symbol. For every grammar, there is a proportionally sized grammar in this form.

A Lempel-Ziv parse [20] of \( T \) cuts \( T \) into \( z \) phrases, so that each phrase \( T[i, j] \) appears earlier in \( T[i', j'] \), with \( i' < i \). It is known that the smallest grammar generating \( T \) must have at least \( z \) rules [28, 5], and that it is possible to convert a Lempel-Ziv parse into a grammar with \( r = O(\lg(N/z)) \) rules [28, 5, 30, 17, 18]. Furthermore, such grammars can be balanced, that is, the parse tree is of height \( O(\lg N) \). By storing the length of the string to which every nonterminal expands, it is easy to access any substring \( T[i, j] \) from its compressed representation in time \( O(j - i + \lg N) \) by tracking down the range in the parse tree. This can be done even on an unbalanced grammar [3]. The total space used by this representation, with a grammar of \( r \) rules, is \( O(r \lg N) \) bits.

### 3.5 Grammar-based indexing

The pattern-matching index of Claude and Navarro [9] builds on a grammar in Chomsky normal form that generates a text \( T[1, N] \), with \( r + 1 \) rules. Let \( s(A) \) be the string generated by nonterminal \( A \). Then they collect the strings \( s(A) \) for all those nonterminals, except the initial symbol \( S \). Let \( C_1, \ldots, C_r \) be the nonterminals sorted lexicographically by \( s(A) \) and let \( B_1, \ldots, B_r \) be the nonterminals sorted lexicographically by the reverse strings, \( s(A)^\text{rev} \). They create a set of points in \( [1, r] \times [1, r] \) so that \((i, j)\) is a point (corresponding to nonterminal \( A \)) if the rule that defines \( A \) is \( A \rightarrow B_i C_j \). Those points are stored in a wavelet tree.

To search for a pattern \( P[1, m] \), they first find the primary occurrences, that is, those that appear when \( B \) is concatenated with \( C \) in a rule \( A \rightarrow BC \). The secondary occurrences, which appear when \( A \) is used elsewhere, are found in a way that does not matter for this paper. To find the primary occurrences, they cut \( P \) into two nonempty parts \( P = P_1P_2 \), in the \( m - 1 \) possible ways. For each cut, they binary search for \( P_{1}^\text{rev} \) in the sorted set \( s(B_1)^\text{rev}, \ldots, s(B_r)^\text{rev} \) and for \( P_2 \) in the sorted set \( s(C_1), \ldots, s(C_r) \). Let \( [x_1, x_2] \) be the interval obtained for \( P_1 \) and \([y_1, y_2]\) the one obtained for \( P_2 \). Then all the points in \( [x_1, x_2] \times [y_1, y_2] \), for all the \( m - 1 \) partitions of \( P \), are the primary occurrences.

To search for \( P_1^\text{rev} \) or for \( P_2 \), the grammar is used to extract the required substrings of \( T \) in time \( O(m + \lg N) \), so the overall search time to find the \( \text{nooc} \) primary occurrences is \( O(m \lg r(m + \lg N) + \lg r \cdot \text{nooc}) \). The space used by the structure is \( O(r \lg N) \) bits. Within this space one can store Patricia trees on the strings \( s(B_i^\text{rev}) \) and \( s(C_i) \), to speed up binary searches and reduce the time to \( O(m(m + \lg N) + \lg r \cdot \text{nooc}) \). Also, one can use the structure of Gąsieniec et al. [14] that, within \( O(r \lg N) \) further bits, allows extracting any prefix/suffix of any nonterminal in constant time per symbol (see also [10]). Since in our search we only access prefixes/suffixes of whole nonterminals, this further reduces the time to \( O(m^2 + \lg r \cdot \text{nooc}) \).

Claude and Munro [8] extend this structure to support document listing on a collection \( D \) of \( D \) string documents, which are concatenated into a text \( T[1, N] \). To each nonterminal
A they associate the increasing list \( \ell(A) \) of the identifiers of the documents (integers in \([1, D]\)) where \( A \) appears. To perform document listing, they find all the primary occurrences \( A \rightarrow BC \) of all the partitions of \( P \), and merge their lists. There is no useful worst-case time bound for this operation other than \( O(nocc \cdot ndoc) \), where \( nocc \) can be much larger than \( ndoc \). To reduce space, they also grammar-compress the sequence of all the \( r \) lists \( \ell(A) \). They also give no worst-case space bound for the compressed lists (other than \( O(rD \lg D) \) bits).

### 4 Our Document Listing Index

We build on the basic structure of Claude and Munro [8]. Our main idea is to take advantage of the fact that the \( nocc \) primary occurrences to detect in Section 3.5 are found as points in the two-dimensional structure, along \( O(\lg r) \) ranges within wavelet tree nodes (recall Section 3.2) for each partition of \( P \). Instead of retrieving the \( nocc \) individual lists, decompressing and merging them [8], we will use the techniques to extract the distinct elements of a range seen in Section 3.1. This will drastically reduce the amount of merging necessary, and will provide useful upper bounds on the document listing time.

#### 4.1 Structure

We store the grammar of \( T \) in a way that it allows direct access for pattern searches, as well as the wavelet tree for the points \((B_i, C_j)\), the Patricia trees, and extraction of prefixes/suffixes of nonterminals, all in \( O(\lg r \cdot N) \) bits.

Consider any sequence \( S_{a,b}[1,q] \) at a wavelet tree node handling the range \([a,b]\) (recall that those sequences are not explicitly stored). Each element \( S_{a,b}[k] = A_k \) corresponds to a point \((i,j)\) associated with a nonterminal \( A_k \rightarrow B_i C_j \). Then let \( L_{a,b} = \ell(A_1) \cdot \ell(A_2) \cdots \ell(A_q) \) be the concatenation of the inverted lists associated with the nonterminals in \( S_{a,b} \), and let \( M_{a,b} = 10^{\ell(A_1)} \cdot 10^{\ell(A_2)} \cdots 10^{\ell(A_q)} \) mark where each list begins in \( L_{a,b} \). Now let \( C_{a,b} \) be the \( C \)-array corresponding to \( L_{a,b} \), as described in Section 3.1. As in that section, we do not store \( L_{a,b} \) nor \( C_{a,b} \), but just the RMQ structure on \( C_{a,b} \), which together with \( M_{a,b} \) will be used to retrieve the unique documents in a range \( S_{a,b}[i,j] \).

Since \( M_{a,b} \) has only \( r \) 1s out of (at most) \( rD \) bits across all the wavelet tree nodes of the same level, it can be stored with \( O(r \lg D) \) bits per level [27], and \( O(r \lg \lg D) \) bits overall. On the other hand, as we will show, \( C_{a,b} \) is formed by a few increasing runs, say \( \rho \) across the wavelet tree nodes of the same level, and therefore we represent its RMQ structure using the technique of Section 3.3. The total space used by those RMQ structures is then \( O(\rho \lg r \cdot \lg(rD/\rho)) \) bits.

Finally, we store the explicit lists \( \ell(B_i) \) aligned to the wavelet tree leaves, so that the list of any element in any sequence \( S_{a,b} \) is reached in \( O(\lg r) \) time by tracking down the element. Those lists, of maximum total length \( rD \), are grammar-compressed as well, just as in the basic scheme [8]. If the grammar has \( r' \) rules, then the total compressed size is \( O(r' \lg(rD)) \) bits to allow for direct access in \( O(\lg(rD)) \) time, see Section 3.4.

In total, our structure uses \( O(r \lg N + r \lg r \lg D + \rho \lg r \lg(rD/\rho) + r' \lg(rD)) \) bits.

#### 4.2 Document listing

A document listing query proceeds as follows. We cut \( P \) in the \( m-1 \) possible ways, and for each way identify the \( O(\lg r) \) wavelet tree nodes (and ranges) where the desired points lie. Overall, we have \( O(m \lg r) \) ranges and need to take the union of the inverted lists of all the points inside those ranges. We extract the distinct documents in each range and then
compute their union. If a range has only one element, then we can track it to the leaves, where its list \( \ell(\cdot) \) is stored, and recover it by decompressing the whole list.

Otherwise, we use in principle the document listing technique of Section 3.1. Let \( S_{a,b}[i,j] \) be a range from where to obtain the distinct documents. We compute \( i' = \text{select}_1(M_{a,b}, i) \) and \( j' = \text{select}_1(M_{a,b}, j + 1) - 1 \), and obtain the distinct elements in \( L_{a,b}[i', j'] \), by using RMQs on \( C_{a,b}[i', j'] \). Recall that, as in Section 3.3, we use a run-length compressed RMQ structure on \( C_{a,b} \). With this arrangement, every RMQ operation takes time \( O(\log \log(rD)) \) plus the time to access two cells in \( C_{a,b} \). Those accesses are made to compare a run head with the leftmost element of the query interval, \( C_{a,b}[i'] \). The problem is that we have not represented the cells of \( C_{a,b} \), and cannot easily compute them on the fly.

Barbay et al. [2, Thm. 3] give a sophisticated representation that determines the position of the minimum in \( C_{a,b}[i', j'] \) without the need to perform the two accesses on \( C_{a,b} \). They need \( \rho \log(rD) + \rho \log(rD/\rho) + O(\rho) + o(rD) \) bits, which unfortunately is too high for us\(^1\).

Instead, we modify the way the distinct elements are obtained, so that comparing the two cells of \( C_{a,b} \) is unnecessary. In the same spirit of Sadakane’s solution (see Section 3.1) we use a bitvector \( V[1, D] \) where we mark the documents already reported. Given a range \( S_{a,b}[i,j] = A_1 \ldots A_j \), we first track \( A_i \) down the wavelet tree, recover and decompress its list \( \ell(A_i) \), and mark all of its documents in \( V \). Note that all the documents in the list \( \ell(\cdot) \) are different. Now we do the same with \( A_{i+1} \), decompressing \( \ell(A_{i+1}) \) left to right and marking the documents in \( V \), and so on, until we decompress a document \( \ell(A_{i+d})[k] \) that is already marked in \( V \). Only now we use the RMQ technique of Section 3.3 on the interval \( C_{a,b}[i', j'] \), where \( i' = \text{select}_1(M_{a,b}, i + d) - 1 + k \) and \( j' = \text{select}_1(M_{a,b}, j + 1) - 1 \), to obtain the next document to report. This technique, as explained, yields two candidates: one is \( L_{a,b}[i'] = \ell(A_{i+d})[k] \) itself, and the other is some run head \( L_{a,b}[k'] \) whose identity we can obtain from the wavelet tree leaf. But we know that \( L_{a,b}[i'] \) was already reported, so we act as if the RMQ was always \( L_{a,b}[k'] \); if the RMQ answer was \( L_{a,b}[i'] \) then, since it is already reported, we should stop. But in this case, \( L_{a,b}[k'] \) is also already reported and we do stop anyway. Hence, if \( L_{a,b}[k'] \) is already reported we stop, and otherwise we report it and continue recursively on the intervals \( C_{a,b}[i', k'-1] \) and \( C_{a,b}[k'+1, j'] \). On the first, we can continue directly, as we still know that \( L_{a,b}[i'] \) is already reported. On the second interval, instead, we must restore the invariant that the leftmost element was already reported. So we find out with \( M \) the list and position \( \ell(A_i)[u] \) corresponding to \( C_{a,b}[k'+1] \) (i.e., \( t = \text{rank}_1(M_{a,b}, k'+1) \) and \( u = k'+1 - \text{select}_1(M, t + 1) \), track \( A_i \) down to its leaf in the wavelet tree, and traverse \( \ell(A_i) \) from position \( u \) onwards, reporting documents until finding one that has been reported. The correctness of this document listing algorithm is proved in Appendix A.

The \( m - 1 \) searches for partitions of \( P \) take time \( O(m^2) \). In the worst case, extracting each distinct document in the range requires an RMQ computation without access to \( C_{a,b} \) \( O(\log \log(rD)) \) time), tracking an element down the wavelet tree \( O(\log r) \) time), and extracting an element from its grammar-compressed list \( \ell(\cdot) \) \( O(\log(rD)) \) time. This adds up to \( O(\log(rD)) \) per document extracted in a range. In the worst case, however, the same documents are extracted over and over in all the \( O(m \log r) \) ranges, and therefore the final search time is \( O(m^2 + m \log \log(rD) \cdot n_{doc}) \).

\(^1\) Even if we get rid of the \( o(rD) \) component, the \( \rho \log(rD) \) term becomes \( O(\epsilon \log^3 N) \) in the final space, which is larger than what we manage to obtain. Also, using it does not make our solution faster.
5 Analysis in a Repetitive Scenario

Our structure uses $O(r \log N + r \log \log D + \rho \log r \log (rD/\rho) + r' \log (rD))$ bits, and performs document listing in time $O(m^2 + n \log r \log (rD) \cdot ndoc)$. We now specialize those formulas under our repetitiveness model. Note that our index works on any string collection; we use the simplified model of the $D - 1$ copies of a single document of length $n$, plus the $s$ edits, to obtain analytical results that are easy to interpret in terms of repetitiveness. We also assume a particular strategy to generate the grammars to show that it is possible to obtain the complexities we give; the actual index may use more sophisticated ones.

5.1 Space

We assume $s \geq D - 1$, since otherwise there will be identical documents, and this is easily reduced to a smaller collection with multiple identifiers per document. The documents are concatenated into $T[1, N]$, where $N \leq nD + s$. Let us make our grammar for $T$ contain the $N^{1/3}$ nonterminals that generate all the strings of length $\frac{1}{3} \log N$. Then it replaces the first document with $O(n/\log N)$ such nonterminals, and builds a balanced parse tree of height $h = O(\log n)$ on top of them, with nonterminal symbol $S$ at the root. On the copies, it first covers them with $D - 1$ copies of $S$. Now, for each edit that occurs on a copy, let $A_1, \ldots, A_h$ be the nonterminals from the leaf (where the edit is applied) to the root $A_h = S$. We create new nonterminals $A'_1, \ldots, A'_h$, so that $h' \leq h + 1$ and $A'_h = S'$ generates the modified document. All the other nonterminals can be reused. Therefore, the maximum height $h'$ of the final nonterminal $S'$ rooting a modified document is $O(\log (n + s))$, which is reached when many of the edits apply to a single copy. The final grammar size is then $r = O(N^{1/3} + n/\log N + s \log (n + s)) = O(n/\log N + s \log N)$, where we used that either $n$ or $s$ is $\Omega(\sqrt{N})$ because $N \leq nD + s \leq n(s + 1) + s$. Once all the edits are applied, we add a balanced tree on top of those $r$ symbols, which asymptotically does not change $r$ (we may also avoid this final tree and access the documents individually, since our accesses never cross document borders).

Let us now bound $\rho$. If there are no edits, then every nonterminal appears in all the documents, so all the lists are of the form $\ell(A) = 1, 2, \ldots, D$. Therefore, all the corresponding $C$ values are $C[k] = k - D$, and $C$ has just one nondecreasing run (the first $D$ values are 0, and thus included in the run too). Let us consider the effect of an edit operation at some document $d$. When we update the upward path $A_1, A_2, \ldots, A_h$ and create nonterminals $A'_1, A'_2, \ldots, A'_h$, to reflect the edit, document $d$ may disappear from all the lists $\ell(A_i)$. Each of those (up to) $h'$ disappeared documents produces a change in $C$, where the cell that pointed to the disappeared position now points earlier, and this may break one run. There are other $h'$ updates due to the creation of the lists for the nonterminals $A'_i$. Overall, array $C$ undergoes $O(\log N)$ run breaks per edit, and therefore it has a total of $\rho = O(s/\log N)$ runs.

The analysis of $r'$ is analogous. When there are no edits and $\ell(A) = 1, 2, \ldots, D$ for all nonterminals $A$, we can represent the lists with a grammar of $O(D)$ symbols generating one list from nonterminal $U$, and then $r - 1$ copies of $U$. Now, an edit in a document $d$ that removes $d$ from the lists of nonterminals $A_1, \ldots, A_h$ produces $O(\log N)$ edits in the lists $\ell(A_1), \ldots, \ell(A_h)$ (and new lists $\ell(A'_i)$ as well). As done for the text, the grammar needs to add $O(\log D)$ nonterminals to modify the copy of $U$ of each list $\ell(A_i)$, from the point where $d$ disappears to the root $U$. The new lists $\ell(A'_i)$ also fit within the same space. Therefore, the final grammar is of size $r' = O(D + s \log N \log D) = O(s \log N \log D)$. Instead of adding a balanced grammar tree over the $r$ resulting nonterminals $U'$, we retain direct pointers to those roots. As a result, the lists, of maximum length $D$, need $O(r' \log D)$ bits and can be
accessed in time $O(\lg D)$. From the wavelet tree, however, we still have to pay also the $O(\lg r)$ time needed to identify the list to access.

Therefore, the total size of the index can be expressed as follows. The $O(r \lg r \lg D)$ bits coming from the sparse bitvectors $M$, is $O(r \lg N \lg D)$ (since $\lg r = \Theta(\lg(n_s)) = \Theta(\lg N)$), and thus it is $O(n \lg \sigma \lg D + s \lg^2 N \lg D)$. This subsumes the $O(r \lg N)$ bits of the grammar and the wavelet tree. The $O(\rho \lg r \lg(rD/\rho))$ bits of the structures $C$ are monotonically increasing with $\rho$, so since $\rho = s \lg N \leq r$, we can upper bound it by replacing $\rho$ with $r$, obtaining $O(r \lg r \lg D)$ as in the space for $M$. Finally, the $O(r' \lg D)$ bits of the explicit inverted lists are $O(s \lg N \lg^2 D)$. Overall, the structures add up to $O((n \lg \sigma + s \lg^2 N) \lg D)$ bits. Note that we can also analyze the space required by Claude and Munro’s structure $[8]$, which is $O(r \lg N)$ bits plus the inverted lists, $O(n \lg \sigma + s \lg N(\lg N + \lg^2 D))$ bits. Although smaller than ours, their search time has no useful bounds.

### 5.2 Time

Our search time is $O(m^2 + m \lg r \lg(rD) \cdot ndoc) = O(m^2 + m \lg^2 N \cdot ndoc)$. The $O(\lg(rD))$ cost corresponds to accessing a list $\ell(A)$ from the wavelet tree, and includes the $O(\lg r)$ time to reach the leaf and the $O(\lg D)$ time to access a position in the grammar-compressed list. It is possible to reduce the $O(\lg r)$ wavelet tree time by spending more space. The trick is to track the positions upwards to the root, not downwards to the leaves, and associate the lists $\ell(A)$ aligned to the root order. It is possible to reach the root position of a symbol in time $O((1/\epsilon) \lg^r r)$ by using $O((1/\epsilon)\lg r)$ bits $[6, 25]$, for any $\epsilon > 0$. By using a constant $\epsilon$ we obtain our main result.

**Theorem 1.** Let collection $D$, of total size $N$, be formed by an initial document of length $n$ plus $D - 1$ copies of it, with $s$ single-character edit operations applied on the copies. Then $D$ can be represented within $O((n \lg \sigma + s \lg^2 N) \lg D)$ bits, so that the $ndoc$ documents where a pattern of length $m$ appears can be listed in time $O(m^2 + m \lg N(\lg D + \lg^r N) \cdot ndoc)$, for any constant $\epsilon > 0$.

We can also obtain other tradeoffs. For example, with $\epsilon = 1/\lg \lg r$ we obtain $O((n \lg \sigma + s \lg^2 N)(\lg D + \lg \lg N))$ bits of space and $O(m^2 + m \lg N(\lg D + \lg \lg N) \cdot ndoc)$ search time.

### 6 Conclusions

We have presented the first document listing index with worst-case space and time guarantees that are useful for repetitive collections. On a collection of size $N$ formed by an initial document of length $n$ and $D - 1$ copies it, with $s$ single-character edits applied on the copies, our index uses $O((n \lg \sigma + s \lg^2 N) \lg D)$ bits and lists the $ndoc$ documents where a pattern of length $m$ appears in time $O(m^2 + m \lg N(\lg D + \lg^r N) \cdot ndoc)$, for any constant $\epsilon > 0$. We also prove a slightly lower space bound on a previous index that had not been analyzed $[8]$, but which has no useful worst-case time bounds for listing.

The space of our index is an $O(\lg D)$ factor away from what can be expected from a grammar-based index. This is the price paid for storing the inverted lists of the nonterminals.

An important question is whether this space factor can be removed, that is, if the inverted lists can be represented within the grammar-compressed size of the text itself.

Another interesting question is whether there exists an index (or a better analysis of this index) whose space and time can be bounded on more general repetitiveness measures of the collection, for example in terms of the number $z$ of Lempel-Ziv phrases into which it can be parsed. In our model it holds $z \leq n/\lg \sigma n + O(s)$, but other kinds of plausible repetitive
collections have $s \gg z$, for example if the edits apply to ranges of documents, or if they involve blocks of text inserted, deleted, or moved around. Typical grammar-based pattern matching indices \cite{9,10} require $O(r \lg N) = O(z \lg^2 N)$ bits in general; it would be good to obtain the same in the document-listing grammar-based indices.

Finally, there is the question of how much of the theoretical improvements over previous work \cite{8} can be translated into practice. This is also a subject of future work. On one hand, our upper bounds are utterly pessimistic when they assume that the same documents will be reported $O(m \lg r)$ times; the average case should be much better. On the other hand, practical improvements are possible over the basic theoretical ideas presented, which should allow us effectively avoid the cases where the previous index deviates significantly from our worst-case time guarantees, without ruining the cases where it performs well. For example, we can list the documents by brute force when the wavelet tree ranges are short, and use the document listing algorithm only on the long ones, where it is worth applying.

References

We prove that our new document listing algorithm is correct. We remind that the algorithm when run on any subrange is correct. Since these were not reported before, by invariant (1) they must be leftmost occurrences in .

Proof. We prove that our new document listing algorithm is correct. We remind that the algorithm proceeds as follows, to find the distinct elements in . It starts recursively with and remembers the documents that have already been reported, globally. To process interval , it considers until finding an already reported element at . Then it finds the minimum in . If has been reported already, it stops; otherwise it reports and proceeds recursively in and in this order. (The algorithm does this without noticing the cases where , but this is correct, as explained in Section 4.2).

Lemma 2. The described algorithm reports the ndoc distinct elements in in steps.

Proof. We prove that the algorithm reports the leftmost occurrence in of each distinct element. In particular, we prove by induction on (and, upon ties, on ) that, when run on any subrange of , (1) every leftmost occurrence in is already reported before processing , and (2) every leftmost occurrence in is reported after processing . Invariant (1) holds for , and the recursive procedure always produces intervals with nondecreasing values of . Then the base case is trivial: the algorithm checks and reports it if it was not reported before. On a larger interval , the algorithm first reports occurrences of distinct elements in . Since these were not reported before, by invariant (1) they must be leftmost occurrences in , and thus after doing this the invariant (1) holds for any range starting at .

Now, we compute the position with minimum in . Note that reports a leftmost occurrence iff . In this case, it has not been reported before and thus it must be reported by the algorithm. The algorithm then recurses on , and finally recurses on . Since those subintervals are inside , we can apply induction. In the call on , the invariant (1) holds and thus by induction we have that after the call the invariant (2) holds, so all the leftmost occurrences in have been reported. After we report too, the invariant (1) also holds for the call on , so by induction all the leftmost occurrences in have been reported when the call returns.

In case , is not a leftmost occurrence in , and moreover there are no leftmost occurrences in , so we can stop since all the leftmost occurrences in .

2 Since does not appear in , the algorithm also works if is reported before the recursive calls, which makes it real-time.
$A[sp, j] = A[sp, d - 1] \cdot A[d, j]$ are already reported. Indeed, if the leftmost occurrence of $A[k]$ is in $A[sp, d - 1]$, then we had already reported it by invariant (1), so the algorithm stops.

Then the algorithm is correct. As for the time, clearly the algorithm never reports the same element twice. The sequential part reports $d - i$ documents in time $O(d - i + 1)$. The extra $O(1)$ can be charged to the caller, as well as the $O(1)$ cost of the subranges that do not produce any result. Each calling procedure reports at least one element $A[k]$, so it can absorb those $O(1)$ costs, for a total cost of $O(ndoc)$.

Abstract

Let \( f : [1..n] \rightarrow [1..n] \) be a function, and \( \ell : [1..n] \rightarrow [1..\sigma] \) indicate a label assigned to each element of the domain. We design several compact data structures that answer various queries on the labels of paths in \( f \). For example, we can find the minimum label in \( f^k(i) \) for a given \( i \) and any \( k \geq 0 \) in a given range \([k_1..k_2]\), using \( n \lg n + O(n) \) bits, or the minimum label in \( f^{-k}(i) \) for a given \( i \) and \( k > 0 \), using \( 2n \lg \sigma + O(n) \) bits, both in time \( O(\lg \sigma/\lg \lg n) \). By using \( n \lg \sigma + o(n \lg \sigma) \) further bits, we can also count, within the same time, the number of labels within a range, and report each element with such labels in \( O(1 + \lg \sigma/\lg \lg n) \) additional time.

Several other possible queries are considered, such as top-\( t \) queries and \( \tau \)-majorities.

1 Introduction

We focus on the representation of integer functions where the domain coincides with the image, \( f : [1..n] \rightarrow [1..n] \). This kind of functions were studied by Munro et al. [10], who focused on how to compute efficiently powers of functions. A positive power is \( f^k(i) \), for a given \( i \in [1..n] \) and \( k \geq 0 \), whereas a negative power returns all the elements in the set \( f^{-k}(i) = \{ j, f^k(j) = i \} \), for a given \( i \in [1..n] \) and \( k > 0 \). They show that \( f \) can be represented within \( n \lg n + O(n) \) bits so that any positive power \( f^k(i) \) is computed in time \( O(1) \), and any negative power \( f^{-k}(i) \) is listed in time \( O(|f^{-k}(i)|) \). The main idea of Munro et al. is summarized in their metaphor “functions are just hairy permutations”, in the sense that the directed graph \( G(V, E) \) where \( V = [1..n] \) and \( E = \{(i, f(i)), i \in [1..n]\} \) has the form of a set of cycles, where a tree may sprout from each node in each cycle (permutations, instead, are decomposed into just a set of cycles).

In this article we go beyond the goal of simply listing the elements of powers of permutations. Instead, we seek to compute summaries on the elements belonging to paths in \( G \). We consider three kinds of paths \( P \):

---

* Supported with Basal Funds FB0001, Conicyt, Chile, and by Fondecyt grant 1-140796, Chile.
1. A positive path is formed by the distinct elements in \( f^{k_1..k_2}(i) = \{ f^k(i), k \in [k_1..k_2] \} \) for a given \( i \in [1..n] \) and \( 0 \leq k_1 \leq k_2 \).

2. A negative path is formed by the distinct elements in \( f^{-k_1..-k_2}(i) = \{ j \in f^{-k}(i), k \in [k_1..k_2] \} \) for a given \( i \in [1..n] \) and \( 0 < k_1 \leq k_2 \).

3. A negative path point is a particular case of a negative path, formed by the elements in \( f^{-k}(i) \), for a given \( i \in [1..n] \) and \( k > 0 \).

In turn, we consider various kinds of summarizations. For maximum generality, let us assume that the elements are assigned a label \( \ell : [1..n] \rightarrow [1..\sigma] \), and we perform summary queries on the labels. We consider the following queries on paths \( P \): (1) Minimum or maximum queries: Return \( \min(\ell(j), j \in P) \) or \( \max(\ell(j), j \in P) \). (2) Selection queries: Return the element of \( P \) with the \( r \)th smallest or largest label, including queries where the value of \( r \) is relative to \( |P| \) such as median queries. (3) Top-\( t \) queries: Return a set \( M \subseteq P \) formed by \( t \) elements with smallest or largest labels in \( P \). (4) \( \tau \)-Majority queries: Return a set of labels whose relative frequency in \( P \) is over \( \tau \), for a given \( 0 \leq \tau < 1 \). (5) Range queries: Let \( R = \{ j \in P, \ell(j) \in [\ell_1, \ell_2] \} \), given \( 1 \leq \ell_1 \leq \ell_2 \leq \sigma \). A counting query asks for \( |R| \), whereas a reporting query requires listing all the elements in \( R \).

As an application of summary queries on paths, suppose we are simulating a system to prepare for situations in which we need to react quickly, e.g., natural disasters or conflicts or critical-equipment failures. We run our simulation through some finite set of states and want to store the traces such that later, given a start state in that set and a number of time-steps, we can quickly return statistics about the states the simulation passes through from that state in that many steps. Of course, we could precompute all the possible answers, but this could take space quadratic in the number of states; we could iterate through all the relevant states at query time, but this could take linear time. If our simulation is deterministic, our problem reduces to storing a function (from states to states, with each state labelled by satellite data) compactly such that we can efficiently answer path queries on it.

The case of positive paths is the easiest. We build on the recent results of He et al. [8] and Chan et al. [3], who give succinct (and also larger) structures for various path queries on trees. Then a relatively simple unfolding and doubling of the cycles in the graph \( G \) allows us to directly apply their results to positive paths, with a small extra time penalty to map from the domain of \( f \) to the nodes of \( G \). For example, we can solve minimum or maximum queries using \( n \lg n + O(n) \) bits and \( O(\lg n / \lg \lg n) \) time, range queries in \( n \lg n + n \lg \sigma + O(n) + o(n \lg \sigma) \) bits and \( O(\lg n / \lg \lg n) \) time per returned element, and selection queries in \( n \lg n + 2n \lg \sigma + O(n) + o(n \lg \sigma) \) bits and \( O(\lg n / \lg \lg n) \) time.

For negative path points, we unroll the cycles in a way that all the desired nodes in any \( f^{-k}(i) \) belong to a contiguous range within a single level of the tree. Then an appropriate layout of the data associated with the node allows us to reduce queries on negative path points to array range queries. Since array ranges are particular cases of tree paths, all the complexities obtained for positive paths are inherited by negative path points, but in addition we can perform other queries that have good solutions on array ranges. For example, we can solve top-\( t \) queries [14] using \( n \lg n + O(n \lg T) \) bits, where \( T \) is the maximum \( t \) value permitted, in time \( O(t + \lg n / \lg \lg n) \). As another example, we can solve \( \tau \)-majority queries using \( n \lg n + (1 + \epsilon) n \lg \sigma \) bits, for any constant \( \epsilon > 0 \), in time \( O(\lg n / \lg \lg n + 1/\tau) \) [1].

The hardest case is the general negative paths. Our queries in this case are mapped into a three-dimensional space, and thus the structures require \( O(n \lg n) \) space in order to offer polylogarithmic times. Still, there is no previous result in this case, and thus it is left open whether those queries can be solved efficiently within linear space.
2 Background

2.1 Rank and select on bitvectors

A bitvector $B[1..n]$ can be represented in $n + o(n)$ bits so as to perform operations rank and select in constant time [5]. Operation $\text{rank}_b(B, i)$, for $b \in \{0, 1\}$ and $i \in [1..n]$, is the number of occurrences of bit $b$ in $B[1..i]$. Operation $\text{select}_b(B, j)$, with $b \in \{0, 1\}$ and $j \in [1..\text{rank}_b(B, n)]$, is the position of the $j$th occurrence of bit $b$ in $B$.

2.2 Permutations and functions

Munro et al. [10] regard a permutation $\pi$ on $[1..n]$ as a directed graph $G = (V, E)$, where $V = [1..n]$ and $E = \{(i, \pi(i)), i \in [1..n]\}$. This graph turns out to be a set of simple cycles, which correspond to the cycle decomposition of $\pi$. Figure 1 (left) shows the graphical representation of permutation $\pi = (3 \, 6 \, 2 \, 7 \, 5 \, 1 \, 4)$, which is decomposed into the cycles $(1 \, 3 \, 2 \, 6)$, $(5)$, and $(4 \, 7)$. A function $f : [1..n] \rightarrow [1..n]$ is then regarded as an extension of permutations, where a general tree may sprout from each node of the cycles. Figure 1 (right) illustrates the case of $f(1..24) = (5, 1, 23, 11, 3, 24, 18, 8, 1, 4, 23, 18, 18, 22, 9, 22, 4, 3, 2, 2, 6, 9, 1, 6)$, which extends the cycles of our example $\pi$.

From the results that are interesting to us, Munro et al. obtain two representations for permutations $\pi$. The first uses $\lg n! + o(n)$ bits and computes any $\pi(i)$ in time $O(1)$ and any $\pi^{-1}(i)$ in time $O(\lg n/\lg \lg n)$. The second uses $\lg n! + O((n/t) \lg n)$ bits, for any $t \leq \lg n$, and computes any $\pi(i)$ in time $O(1)$ and any $\pi^{-1}(i)$ in time $O(t)$. For functions, they can compute any positive power $f^k(i)$, with $k \geq 0$, or negative power $f^{-k}(i) = \{j, f^k(j) = i\}$, with $k > 0$, in time $O(t)$ and $O(t + |f^{-k}(i)|)$, respectively, using $n \lg n(1 + 1/t)$ bits of space, for any $t \leq \lg n$.

2.3 Path queries on trees

He et al. [8] and Chan et al. [3] showed how to represent a tree where the nodes have labels (or weights) in succinct space so as to support various queries on the paths of the tree. Let us regard the trees as acyclic connected graphs $G(V, E)$; then a path is a sequence of nodes.
Given a general ordinal tree of \( n \) nodes, where each node \( v \) has a label \( \ell(v) \in [1..\sigma] \), they support the following queries on paths \( P \) of the tree, among others:

1. **Minimum/maximum queries**, that is, find the node holding the smallest (resp. largest) label in \( P \), are solved in time \( O(n \log \sigma) \) with a structure using \( O(n \log \sigma) \) bits of space on top of the raw data, for any \( n \geq 1 \), where \( \alpha \) is the inverse of the Ackermann function [3].

2. **Selection**, that is, find the node holding the \( r \)-th smallest label in \( P \), is solved in time \( O((r + 1)(\log \sigma + \log \log \sigma)) \) [8]. By using more space, it is possible to match the same results of two-dimensional range queries [3].

These structures include an \( O(n) \)-bit representation of the tree topology. There are several alternatives (see [11, Ch. 8]) using \( 2n + o(n) \) bits and supporting a wide set of navigation operations on trees. For positive paths, it turns out that the representations for the path queries used in this section [8, 3] support in constant time a few queries that will be useful:

- Mapping from each tree node \( v \) to a unique identifier \( \text{id}(v) \in [1..n] \), and from an identifier \( i \in [1..n] \) to the tree node, \( \text{node}(i) \).
- Level ancestor queries, that is, given a node \( v \) and a distance \( d \), \( \text{anc}(v, d) \) is the ancestor of \( v \) at distance \( d \) (e.g., \( \text{anc}(v, 0) = v \) and \( \text{anc}(v, 1) \) is the parent of \( v \)).
- The depth of a node, \( \text{depth}(v) \), where the depth of the root is 0.
- The leftmost leaf of the subtree of a node, \( \text{leftmost}(v) \).
- The lowest common ancestor of two nodes, \( \text{lca}(u, v) \).

For negative paths, instead, we will use the Fully-Functional (FF) representation [15], which represents the tree using \( 2n \) parentheses: the tree is traversed in depth-first order, writing an opening parenthesis when we reach a node and a closing one when we leave it. Within \( 2n + o(n) \) bits it supports in constant time all of the above operations, plus \( \text{fwd}(x, d) \) and \( \text{bwd}(x, d) \), defined as follows. Let \( \text{excess}(y) \) be the number of opening minus closing parentheses up to position \( y \) in the parentheses sequence. Then \( \text{fwd}(x, d) \) (resp. \( \text{bwd}(x, d) \)) finds the closest position \( y \) to the right (resp. to the left) of \( x \) where \( \text{excess}(y) = \text{excess}(x) + d \). For example, if there is an opening (resp. closing) parenthesis at \( x \), its corresponding closing (resp. opening) parenthesis is at \( \text{close}(x) = \text{fwd}(x, -1) \) (resp. \( \text{open}(x) = \text{bwd}(x, 0) + 1 \)).

### 2.4 Range queries on arrays

A much better studied particular case of path queries is that of range queries on an array \( A[1..\sigma] \) of labels in \([1..\sigma]\). The following is a brief selection from a number of results reported in the literature:

1. **Minimum queries**, where it is possible to find the position of a minimum in any range \( A[i..j] \) in \( O(1) \) time with a structure that uses \( 2n + o(n) \) bits and does not access \( A \) [6]. An analogous result holds for maximum queries.

2. **Selection queries**, where we can set at construction time a maximum value \( R \) of \( r \) that can be used in queries, and then a structure using \( O(n \log R) \) bits, without accessing \( A \),

---

1 They actually handle undirected graphs, supporting paths between any two nodes \( u \) and \( v \). Those can be easily decomposed into two directed paths, from \( u \) to \( \text{lca}(u, v) \) and from \( v \) to \( \text{lca}(u, v) \), where \( \text{lca} \) is the lowest common ancestor operation.
can answer queries in optimal time $O(1 + \log r/\log \log n)$ [14]. Note that we can set $R = n$ for maximum generality.

3. Top-$t$ queries, that is, finding $t$ elements in $A[i..j]$ with largest labels, can be answered in optimal time $O(t)$ with a structure that uses $O(n \log T)$ bits and does not access $A$, where $T$ is an upper bound on the values of $t$ that can be queried [14].

4. $\tau$-majority queries, that is, finding the labels whose relative frequencies in $A[i..j]$ are above $\tau$. This can be solved in optimal time $O(1/\tau)$ and $O(1 + \epsilon)nH(\ell) + o(n)$ bits, for any constant $\epsilon > 0$; this representation contains $A$ in compressed form. The space can be reduced to $nH(\ell)(1 + o(1)) + o(n)$ bits, and still obtain any time in $\omega(1/\tau)$ [1].

5. Range counting can be performed in $O(1 + \log \sigma/\log \log n)$ time, and reporting of the $r$ results can be done in $O((r + 1)(1 + \log \sigma/\log \log n))$, using $n \log \sigma + o(n \log \sigma)$ bits [2].

### 2.5 Range queries in two dimensions

When the ranges are two-dimensional and the points have weights, most of the queries require linear and even super-linear space. Some examples in the literature follow.

1. The top-$t$ elements in a two-dimensional range of an $n \times n$ grid with points having weights in $[1..\sigma]$ can be computed in time $O((t + \log n)\log^2 n)$, for any constant $\epsilon > 0$, with a data structure that uses $O(n \log n)$ bits [12, Lem. 7.1]. With $t = 1$, this gives a structure for range minima or maxima.

2. The $r$th largest element in a two-dimensional range can be obtained in time $O(\ell \log n \log \ell \sigma)$ with a structure using $n \log n \log \ell \sigma + O(n \log \sigma)$ bits, for any $\ell \in [2, \sigma]$ [13].

3. The same structure of the previous point can be used to find the $\tau$-majorities in a range in time $O((1/\tau)\ell \log n \log \ell \sigma)$ [13].

4. Range counting queries in three dimensions (or in two dimensions and labels) can be carried out in time $O((\log n/\log \log n)^2)$ with a structure that uses $O(n \log^2/\log \log n)$ bits of space [9]. Within that space, each point can be reported in time $O((\log n/\log \log n)^2)$ [9]. By raising the space to $O(n \log^{2+\epsilon} n)$ bits, for any constant $\epsilon > 0$, the time to report $r$ points is reduced to $O(r + \log \log n)$ [4].

### 3 Positive Paths

A positive path of the form $f^{k_1..k_2}(i)$ can be handled by converting the graph $G$ that represents $f$ (recall Figure 1 (right)) into a single tree. The transformation is as follows:

1. We cut each cycle $v_1 \rightarrow v_2 \rightarrow \ldots \rightarrow v_c \rightarrow v_1$ at an arbitrary position, say removing the edge $v_c \rightarrow v_1$. The result is a directed tree rooted at $v_c$ (with arrows pointing from children to parents) where the cycle edges form the leftmost path.

2. We add a new leaf per cycle, which will be the leftmost child of $v_1$.

3. We add an artificial root, which will be the parent of the roots $v_c$ of all the cycles.

4. We represent the resulting tree using the data structures of Section 2.3, for whichever query we want to answer. The representation must support in constant time the operations id, node, anc, depth, leftmost, and lca.

5. We store a bitvector $B[1..n + l + 1]$, where $l \leq n$ is the number of leaves added, or equivalently the number of cycles in $f$, so that $B[i] = 1$ iff the tree node with identifier $i$ is one of the original nodes of $G$. We give rank and select support to $B$, so as to map the tree node identifiers in $[1..n + l + 1]$ of the nodes that are in $G$ to the interval $[1..n]$.

6. We store a permutation $\pi$ that goes from the mapped node identifiers in $[1..n]$ to the corresponding domain elements, using the representation of Section 2.2.
Figure 2 exemplifies our construction on the function of Figure 1. The permutation \( \pi \) is displayed in the form of numbers associated with the nodes. Note how we have broken the cycle \( 3 \rightarrow 23 \rightarrow 1 \rightarrow 5 \rightarrow 3 \), for example.

Consider now a positive path query \( f^{k_1,k_2}(i) \). In the simplest case, we proceed as follows:

1. We compute \( v = \text{node}(\text{select}_1(B, \pi^{-1}(i))) \), the node where the path query will start.
2. We compute the path extremes \( v_s = \text{anc}(v,k_1) \) and \( v_e = \text{anc}(v,k_2) \).
3. We carry out the desired query on the tree path from \( v_s \) to \( v_e \).
4. Any node \( u \) returned by the query is mapped back to a domain value in constant time using \( \pi(\text{rank}_1(B, \text{id}(u))) \).

In our example, we can compute a query on \( f^{1,3}(4) = (11, 23, 1) \) with this technique. However, consider \( f^{1,4}(15) \). Our technique maps the path to the domain elements \( (9, 1, 5, ??) \), whereas the correct domain elements to include were \( (9, 1, 5, 3) \). This is because the path goes through the node \( v_e \) where we have cut the cycle. In general, both \( k_1 \) and \( k_2 \) may be several times larger than the cycle length.

To handle this situation, we use the cycle as follows. First, if \( k_1 \geq \text{depth}(v) \), then we set \( v_s \leftarrow \text{anc}(v_1, (k_1 - \text{depth}(v)) \mod c) \), where \( v_1 \) is the lowest node of the cycle and \( c \) is the cycle length. Similarly, if \( k_2 \geq \text{depth}(v) \), we set \( v_e \leftarrow \text{anc}(v_1, (k_2 - \text{depth}(v)) \mod c) \). For this we compute \( v_e = \text{anc}(v, \text{depth}(v) - 1) \), then \( v_1 = \text{anc} (\text{leftmost}(v_e), 1) \) and \( c = \text{depth}(v_1) \).

However, \( v_e \) might not be an ancestor of \( v_s \) after this transformation, that is, \( \text{depth}(v_e) > \text{depth}(v_s) \) or \( \text{anc}(v_s, \text{depth}(v_s) - \text{depth}(v_e)) \neq v_e \). This means that the positive path is cut into two tree paths: one from \( v_s \) to \( v_e \), and the other from \( v_1 \) to \( v_e \). In our example, \( f^{1,4}(15) \) is cut into the paths \( (9, 1, 5) \) and \( (3) \).

This can be handled if the query is decomposable, that is, we can obtain the answer from the results on the two paths. For example, range counting and reporting are obviously decomposable, whereas range minima (if we do not store the labels, as in the solution of Section 2.3) and selection queries are not decomposable.

A final issue is that, if \( k_2 - k_1 \geq c \), we may visit the same domain values several times along the positive path. Since we want to consider each distinct element only once, we can solve this problem by splitting the query into up to three paths: one inside the tree where \( v \) belongs that sprouts from the cycle, and two on the cycle. We first compute \( v' = \text{lea}(v, v_1) \), to find the cycle node where the tree of \( v \) sprouts. Then a first path to consider, if \( k_1 < d = \text{depth}(v) - \text{depth}(v') \), is the one corresponding to \( [k_1, \min(k_2, d - 1)] \).
If \( k_2 \geq d \), we then consider paths on the cycle, starting at node \( v' \) and with the range \([k_1', k_2'] = [\max(0, k_1 - d), k_2 - d] \). If \( k_2' - k_1' \geq c - 1 \), we simply include the whole cycle, with the path from \( v_1 \) to \( v_c \). Otherwise, we proceed as before.

Algorithm 1, in Appendix A, gives the complete procedure. We have then Theorem 1, where the extra time is the one spent to compute \( \pi^{-1}(i) \) and the extra space is that of storing \( \pi \) and \( B \).

**Theorem 1.** Let \( f : [1..n] \to [1..n] \) be a function and \( \ell : [1..n] \to [1..\sigma] \) an assignment of labels to the domain elements. Let there be a tree representation that performs in constant time the operations \( \text{id}, \text{node}, \text{anc}, \text{depth}, \text{leftmost}, \text{lea} \), and in addition it solves a certain decomposable path query on \( n \)-node trees with labels in \([1..\sigma]\) in \( T(n, \sigma) \) time, using in total \( S(n, \sigma) \) bits of space. Then, there exists a data structure using \( n \lg n + O(n) + S(n, \sigma) \) bits that answers the same query on the positive paths of \( f \) in time \( O(\lg n/\lg \lg n) + T(n, \sigma) \).

There exists another data structure using \( n(1 + 1/t) + S(n, \sigma) \) bits that answers the query in time \( O(t) + T(n, \sigma) \), for any \( t \leq \lg n \).

By considering the range queries of He et al. [8] (Section 2.3), we derive Corollary 2.

**Corollary 2.** Let \( f : [1..n] \to [1..n] \) be a function and \( \ell : [1..n] \to [1..\sigma] \) an assignment of labels to the domain elements. Then, there exists a data structure using \( n \lg n + nH(\ell) + O(n) + o(n \lg \sigma) \) bits that answers counting queries on the positive paths of \( f \) in time \( O(\lg n/\lg \lg n) \), and also reports those \( r \) results in time \( O(\lg n/\lg \lg n + r(1 + \lg \sigma/\lg \lg n)) \), where \( H(\ell) \leq \lg \sigma \) is the entropy of the distribution of the values in \( \ell \).

### Non-decomposable path queries

When the query is not decomposable, we cannot allow splitting paths. Instead, we unroll the cycles twice, as illustrated in Figure 3. More formally:

1. We cut each cycle \( v_1 \to v_2 \to \ldots \to v_c \to v_1 \) as before, removing the edge \( v_c \to v_1 \) and leaving a tree rooted at \( v_c \).
2. We add a leaf as the leftmost child of \( v_1 \), as before.
3. We add an upward path per cycle, starting at each tree root \( v_c \), which repeats the cycle with copies of the nodes. That is, we add edges \( v_c \to v_c' \to v_c'' \to \ldots \to v_c'_{c-1} \). Each of the new nodes \( v_c' \) is assigned the same label of \( v_c \).
4. We add an artificial root, which will be the parent of all the nodes \( v_c'_{c-1} \) (or of the node \( v_1 = v_c \) for cycles of length 1, since in those cases no \( v_c' \) nodes are added).
5. We represent the resulting tree using the data structures of Section 2.3, as before.
6. We store a bitvector \( B[1..n + g] \), where \( g \leq n + 1 \) is the number of nodes added, so that \( B[i] = 1 \) iff the tree node with identifier \( i \) is one of the original nodes of \( G \). As before, we give rank and select support to \( B \).
7. We store a permutation \( \pi \) that goes from the mapped node identifiers in \([1..n]\) to the corresponding domain elements, as before.

We can now compute \( v_c'_{c-1} = \text{anc}(v, \text{depth}(v') - 1) \), \( v_1 = \text{anc}(\text{leftmost}(v_c')_{c-1}, 1) \), \( c = (\text{depth}(v_1) + 1)/2 \), and \( v_c = \text{anc}(v_1, c - 1) \). We also compute \( v' = \text{lea}(v_1, v) \) as before. There are two cases. The first is that the path starts inside the subtree of \( v' \), that is, if \( k_1 < d = \text{depth}(v') - \text{depth}(v') \). In this case, we set \( v_c = \text{anc}(v, k_1) \). Then, if \( k_2 - d < c \), we set \( v_c = \text{anc}(v, k_2) \); otherwise we set \( v_c = \text{anc}(v', c - 1) \). Finally, we run the tree path query from \( v_s \) to \( v_c \).

The other case is that the path lies completely on the cycle, that is, \( k_1 \geq d \). We can first exclude the condition \( k_2 - k_1 \geq c \), as in this case we simply query the path from \( v_1 \) to \( v_c \).
There exists another data structure using queries on trees.

If \( k_2 - k_1 < c \), we find \( v_s \) inside the path that goes from \( v_1 \) to \( v_e \): If \( \text{depth}(v) - k_1 \geq c \), we set \( v_s = \text{anc}(v, k_1) \); otherwise we set \( v_s = \text{anc}(v_1, ((e - 1) - (\text{depth}(v) - k_1)) \mod c) \). We then do the same to compute \( v_e \) with \( k_2 \). Finally, if \( v_e \) is deeper than \( v_s \), we recompute \( v_e = \text{anc}(v_e, c) \). Now we can safely run the tree path query from \( v_s \) to \( v_e \).

A final issue is how to map back the nodes \( u = v_i' \) that the algorithm may return. Note that we know the cycle where the query was performed, so we know \( c \) and \( v_1 \). Thus, if \( \text{depth}(u) < c \), we know that \( u \) is a created node, and replace it with \( \text{anc}(v_1, (c - 1) - \text{depth}(u)) \) before mapping it to the domain of \( f \). Algorithm 2, in Appendix A, gives the pseudocode.

Since we have up to \( n \) newly created nodes for which we have to store labels, we have Theorem 3.

**Theorem 3.** Let \( f : [1..n] \rightarrow [1..n] \) be a function and \( \ell : [1..n] \rightarrow [1..\sigma] \) an assignment of labels to the domain elements. Let there be a tree representation that performs in constant time the operations \( \text{id}, \text{node}, \text{anc}, \text{depth}, \text{leftmost}, \text{and lea} \), and it addition it solves a certain non-decomposable path query on \( n \)-node trees with labels in \([1..\sigma]\) in \( T(n, \sigma) \) time, using in total \( S(n, \sigma) \) bits of space. Then, there exists a data structure using \( n \log n + O(n) + S(2n + 1, \sigma) \) bits that answers the same query on the positive paths of \( f \) in time \( O((\log n / \log \log n) + T(2n + 1, \sigma)) \). There exists another data structure using \( n \log n (1 + 1/t) + S(2n + 1, \sigma) \) bits that answers the query in time \( O(t) + T(2n + 1, \sigma) \), for any \( t \leq \log n \).

By considering the minimum/maximum and the selection queries of He et al. [8] (Section 2.3), we derive Corollaries 4 and 5.

**Corollary 4.** Let \( f : [1..n] \rightarrow [1..n] \) be a function and \( \ell : [1..n] \rightarrow [1..\sigma] \) an assignment of labels to the domain elements. Then, there exists a data structure using \( n \log n + O(n) \) bits that answers minimum/maximum queries on the positive paths of \( f \) in time \( O((\log n / \log \log n)) \). There exists another structure using \( (1 + \epsilon)n \log n + O(m) \) bits, for any constant \( \epsilon > 0 \) and any \( m \geq n \), that answers the queries in time \( \alpha(m, n) \).

**Corollary 5.** Let \( f : [1..n] \rightarrow [1..n] \) be a function and \( \ell : [1..n] \rightarrow [1..\sigma] \) an assignment of labels to the domain elements. Then, there exists a data structure using \( n \log n + 2nH(\ell) + O(n) + o(n \log \sigma) \) bits that answers selection queries on the positive paths of \( f \) in time \( O((\log n / \log \log n)) \), where \( H(\ell) \leq \log \sigma \) is the entropy of the distribution of the values in \( \ell \).
Figure 4 The same tree for decomposable positive queries (without the extra root), showing how the levels are deployed to aid in negative path points.

4 Negative Path Points

Figure 4 shows the same tree of Figure 2, now showing clearly the resulting levels of the tree, and without the extra root. The result is a forest, which we will store with the FF representation [15]. The figure illustrates an important point: all the nodes in $f^{-k}(i)$ correspond to the descendants at distance $k$ of the node corresponding to $i$. For example $f^{-2}(1) = \{3, 11, 22, 15, 20, 19\}$. These form a range if we deploy the nodes in levelwise order.

Just as for positive paths, we will store a bitvector $B$ indicating which nodes are originally in $G$ (i.e., not the added leaves) and a permutation $\pi$ on $[1..n]$ mapping from the identifiers of those nodes in $G$ (after being mapped to $[1..n]$ using $B$) to domain elements. The information on the nodes (such as the labels) will be stored in levelwise order, with a permutation $\rho$ on $[1..n]$ mapping from the levelwise deployment to the tree identifier of the node. Let $v = \text{node}(\text{select}_1(B, \pi^{-1}(i)))$ be the node corresponding to domain element $i$, and assume $v$ is not on the cycle of its component in $G$. Then the elements of $f^{-k}(i)$ are the descendants of $v$ at distance $k$. The leftmost such descendant is found with $v_1 = \text{fwd}(v, k)$, whereas the rightmost one is $v_2 = \text{open}(\text{bwd}(\text{close}(v), k + 1) + 1)$. Then the range of values where the information on the elements of $f^{-k}(i)$ is stored is $[\rho^{-1}(\text{rank}_1(B, \text{id}(v_1))), \rho^{-1}(\text{rank}_1(B, \text{id}(v_2)))]$. Note that any element at position $j$ in the levelwise deployment can be converted into a domain element with $\pi(\rho(j))$. Figure 4 shows how $f^{-2}(9)$ is mapped to the range containing $(16, 14)$, which is within the level containing $(18, 4, 16, 14)$ (disregard for now bitvector $L$ and the way levels are interlaced in the array).

When $v$ is on a cycle (of length $c$), then we can go to its predecessor in the cycle (taking the arrow backwards) and collect the descendants at distance $k - 1$ in its sprouting tree, then to its predecessor and collect its descendants at distance $k - 2$, and so on. Given the way we have converted $G$ into a tree, all these nodes are indeed the descendants of $v$ at distance $k$; consider again $f^{-2}(1)$ in Figure 4. However, the situation can be more complicated because, if the trees sprouting from the cycle are tall enough, then we could run over the whole cycle in backward direction and return again to $v$, now looking for descendants at distance $k - c$. Therefore, not only we have to include the descendants of $v$ at distance $k$, but also all the elements in the whole tree where $v$ belongs at depths $\text{depth}(v) + k - c$, $\text{depth}(v) + k - 2c$, and so on.
To handle this case, we will store the levelwise information on the nodes of each tree of the forest in an interlaced order of the levels: levels 1, c + 1, 2c + 1, and so on, then levels 2, c + 2, 2c + 2, and so on, until levels c, 2c, 3c, and so on. A bitvector L[1..n] with rank and select support will mark, in the levelwise ordered domain, the first node at a level of the form l + kc in each tree, for all 1 ≤ l ≤ c. Figure 4 shows the levelwise deployment. The nodes of the first tree are listed as 5, 18, 4, 16, 14 for l = 1, then 1, 7, 12, 13, 10, 17 for l = 2, then 23, 9, 2 for l = 3, and finally 3, 11, 22, 15, 20, 19 for l = 4. The following two trees are then listed as 6, 24, 21 and 8. The bitvector L marks the beginnings of the change in tree or in l.

With this arrangement, we only have to find as before \( p_2 = \rho^{-1}(\text{rank}_1(B, \text{id}(v_2))) \), the second endpoint of the range, and then \( p_1 = \text{select}_1(L, \text{rank}_1(L, p_2)) \), the beginning of the nodes of the tree of \( v_2 \) with its same \( l \) value. Figure 4 shows how \( v_2 \) is found for \( f^{-2}(23) \), and then the range includes up to the beginning of \( l = 1 \) in its tree, to contain (5, 18, 4).

The final issue is how to determine if \( v \) is or not on the cycle. We can do this by computing, similarly to the positive paths, \( v_c = \text{anc}(v, \text{depth}(v)) \), \( v_0 = \text{leftmost}(v_c) \) as the leftmost leaf,\(^2\) and then \( v \) is in the cycle if and only if \( v_0 \) descends from \( v \), that is, \( v \leq v_0 \leq \text{close}(v) \).

Finally, we can build on the levelwise deployment of the node data any array range query data structure we desire. Algorithm 3, in Appendix A, shows the pseudocode.

The time per query is that of the array range query, plus the time needed to compute \( \pi^{-1} \) and \( \rho^{-1} \) a constant number of times; answers are converted back to domain values by computing \( \rho \) and \( \pi \) in constant time. Apart from the array range query structures, we are storing two permutations and some bitvectors. We then have Theorem 6.

\[\textbf{Theorem 6.} \text{ Let } f : [1..n] \rightarrow [1..n] \text{ be a function and } \ell : [1..n] \rightarrow [1..\sigma] \text{ an assignment of labels to the domain elements. Let there be an array range query data structure that, on an array } A[1..n] \text{ of values in } [1..\sigma], \text{ answers queries in time } T(n, \sigma) \text{ using } S(n, \sigma) \text{ bits of space. Then, there exists a data structure using } 2n \lg n + O(n) + S(n, \sigma) \text{ bits that answers the same query on the negative path points of } f \text{ in time } O(\lg n/\lg \lg n) + T(n, \sigma). \text{ There exists another data structure using } 2n \lg n(1 + 1/t) + S(n, \sigma) \text{ bits that answers the query in time } O(t) + T(n, \sigma), \text{ for any } t \leq \lg n.\]

By considering the various array range queries of Section 2.4, we can derive Corollaries 7 to 10, among others.

\[\textbf{Corollary 7.} \text{ Let } f : [1..n] \rightarrow [1..n] \text{ be a function and } \ell : [1..n] \rightarrow [1..\sigma] \text{ an assignment of labels to the domain elements. Then, there exists a data structure using } 2n \lg n + O(n) \text{ bits that finds the elements of } f^{-k}(i) \text{ with the minimum and the maximum labels, for any } i \in [1..n] \text{ and } k > 0, \text{ in time } O(\lg n/\lg \lg n). \text{ There exists another data structure using } 2n \lg n(1 + 1/t) + O(n) \text{ bits that answers the query in time } O(t), \text{ for any } t \leq \lg n.\]

\[\textbf{Corollary 8.} \text{ Let } f : [1..n] \rightarrow [1..n] \text{ be a function and } \ell : [1..n] \rightarrow [1..\sigma] \text{ an assignment of labels to the domain elements. Then, there exists a data structure using } 2n \lg n + O(n \lg R) \text{ bits that finds the element with the rth largest label in } f^{-k}(i), \text{ for any } i \in [1..n], \text{ and } 1 \leq r \leq R, \text{ in time } O(\lg n/\lg \lg n). \text{ It can also list the } r \text{ elements with the largest or smallest values in } f^{-k}(i) \text{ in time } O(r + \lg n/\lg \lg n).\]

\[\textbf{Corollary 9.} \text{ Let } f : [1..n] \rightarrow [1..n] \text{ be a function and } \ell : [1..n] \rightarrow [1..\sigma] \text{ an assignment of labels to the domain elements. Then, there exists a data structure using } 2n \lg n + (1 + \text{ This operation can be computed in this representation with } \text{select}_j(\text{rank}_j(v_c) + 1) - 1 \text{ on the sequence of parentheses, which has rank and select support.}\]

\[1 \leq j \leq \sigma.\]
There exists another data structure using labels to the domain elements. Then, there exists a data structure using $O(n \log n)$ bits that answers the same query on the negative paths of $f^{-k}(i)$, for any $i \in [1..n]$, $k > 0$, and $0 < \tau < 1$, in time $O(1/\tau + \lg n/\lg \lg n)$.

**Corollary 10.** Let $f : [1..n] \rightarrow [1..n]$ be a function and $\ell : [1..n] \rightarrow [1..\sigma]$ an assignment of labels to the domain elements. Then, there exists a data structure using $2n \log n + nH(\ell) + o(n \log \sigma) + O(n)$ bits, where $H(\ell)$ is the entropy distribution of the labels, that counts the number of labels of $f^{-k}(i)$ within a range, for any $i \in [1..n]$, $k > 0$, and range of labels, in time $O(\log n/\log \log n)$. It can then list these $r$ elements in time $O(\log n/\log \log n + r(1 + \log \sigma/\log \log n))$.

### 5 Negative Paths

For ranges of negative values of $k$, $f^{-[k_1..k_2]}(i)$, our solution maps the queries into two-dimensional ranges, which require more space and/or time than previous ones. We preserve the same tree as in Section 4, but this time the mapping from nodes $v$ is done to pairs (preorder($v$), depth($v$)). Here preorder($v$) = id($v$) is the preorder of the node in the FF representation. Therefore, once we have mapped the domain element $i$ to a tree node $v$, and determined that $v$ is on the cycle, we have that the query encompasses the two dimensional range $[\text{preorder}(v) .. \text{preorder}(v) + \text{subtree size}(v) - 1] \times [\text{depth}(v) + k_1 .. \text{depth}(v) + k_2]$. All these operations are supported in constant time with the FF representation [15]. We now perform the desired query on a structure that handles two-dimensional points (possibly with labels). The returned points $(p, d)$ are then mapped to the nodes with preorder $p$, node(p), which is also supported in constant time.

For the case where $v$ is on the cycle, we will use another arrangement. Note that we want to consider, in addition to the previous range, all the nodes in the tree of $v$ with a depth that is between $d_1 = \text{depth}(v) + k_1$ and $d_2 = \text{depth}(v) + k_2$, modulo $c$, but not reaching the range $[d_1, d_2]$, as that one is already handled. To this end, we will map the nodes $v$ to pairs $(\text{depth}(v) \text{ div } c, \text{depth}(v) \text{ mod } c)$, and will query for the points in the range $[0, d_2 \text{ div } c - 1] \times [d_1 \text{ mod } c .. d_2 \text{ mod } c]$. If, however, $d_1 \text{ mod } c > d_2 \text{ mod } c$, then we split the second range into $[d_1 \text{ mod } c .. c - 1]$ and $[0, d_2 \text{ mod } c]$.

An exception occurs if $k_2 - k_1 \geq c$, since then the two types of ranges overlap and we could count points twice. In this case we take, in this second arrangement, the range $[0, d_2 \text{ div } c - 1] \times [0, c - 1]$, and reduce the range within the subtree of $v$ to $[\text{preorder}(v) .. \text{preorder}(v) + \text{subtree size}(v) - 1] \times [(d_2 \text{ div } c) .. d_2]$. Note that in this case we have to complete the query from the results of up to 3 two-dimensional ranges, so the query must be decomposable. We then obtain Theorem 11.

**Theorem 11.** Let $f : [1..n] \rightarrow [1..n]$ be a function and $\ell : [1..n] \rightarrow [1..\sigma]$ an assignment of labels to the domain elements. Let there be a two-dimensional range query data structure that, on an $n \times n$ grid with values in $[1..\sigma]$, answers decomposable queries in $T(n, \sigma)$ time using $S(n, \sigma)$ bits of space. Then, there exists a data structure using $2n \log n + O(n) + S(n, \sigma)$ bits that answers the same query on the negative paths of $f$ in time $O(\log n/\log \log n + T(n, \sigma))$. There exists another data structure using $2n \log n (1 + 1/\tau) + S(n, \sigma)$ bits that answers the query in time $O(t) + T(n, \sigma)$, for any $t \leq \log n$.

We can combine the theorem with various results on querying two-dimensional grids of points with labels (or weights); recall Section 2.5. We obtain Corollaries 12 and 13.

**Corollary 12.** Let $f : [1..n] \rightarrow [1..n]$ be a function and $\ell : [1..n] \rightarrow [1..\sigma]$ an assignment of labels to the domain elements. Then, there exists a data structure using $O(n \log n)$ bits...
Path Queries on Functions

that answers minima and maxima queries on the negative paths of \( f \) in time \( O(\lg^{1+\epsilon}n) \), and top-\( t \) queries in time \( O((t+\lg n)\lg^{\epsilon}n) \), for any constant \( \epsilon > 0 \).

**Corollary 13.** Let \( f : [1..n] \to [1..n] \) be a function and \( \ell : [1..n] \to [1..\sigma] \) an assignment of labels to the domain elements. Then, there exists a data structure using \( O(n\lg^{2}n/\lg \lg n) \) bits that answers range counting queries on the negative paths of \( f \) in time \( O((\lg n/\lg \lg n)^2) \), and reports the \( r \) values in time \( O((r+1)(\lg n/\lg \lg n)^2) \). By using slightly more space, \( O(n\lg^{2+\epsilon}n) \) bits for any constant \( \epsilon > 0 \), the time to report is reduced to \( O(r + \lg \lg n) \).

### 6 Conclusions

Munro et al. [10] studied how to represent an integer function \( f : [1..n] \to [1..n] \) so as to efficiently find all the elements of positive and negative powers of \( f \). We have now considered, for the first time, queries on ranges of positive or negative powers of \( f \). For positive powers, we essentially retain optimal storage space and almost match the best results of path queries on trees [8, 3]. Negative powers lead to a set of domain values. For a single negative power, we basically double the space while almost retaining the performance of the corresponding array range query. For a range of negative powers, we resort to three-dimensional range queries, where time and space are essentially multiplied by \( O(\lg n) \).

Our results consider queries on arbitrary labels on \([1, \sigma]\) attached to the domain elements. Appendix B gives a few improved results for the simpler case where the queries are run over the domain elements themselves.

This is the first study on this problem, and it is not clear whether the results can be improved, in particular it is not clear if queries on ranges of negative powers of \( f \) must resort to three-dimensional range queries.

### References

A Pseudocodes

We give detailed pseudocodes for the main procedures described in the paper. In Algorithm 1, it is possible to reduce the case of three paths to two, since those of lines 9 and 23 can be concatenated into one, but we opt for simplicity.

B Functions Without Labels

In the simple case where the function has no assigned labels, or said another way, we may assume \( f(i) = i \) for the queries, we can do better than Corollaries 2 and 5. Both path query structures [8] store the sequence of labels (now domain elements) in node identifier order, and represent it with a wavelet tree [7]. This structure allows us, with a query similar to select, to find the occurrence of element \( i \), thus effectively computing \( \pi^{-1}(i) \), in time \( O(\lg n / \lg \lg n) \). Instead of returning the node identifier, they may return the label, that is, the domain element, by accessing the wavelet tree in the same time. Therefore, they do not require the permutation to map from elements to nodes. In the case of Corollary 5, where we have duplicated nodes \( v'_i \), we may use the select-like operation to find the two places where an element is mentioned in the labels, and choose the one with largest depth to avoid starting
Path Queries on Functions

\[ \text{Algorithm 1: Computing decomposable queries on positive paths.} \]

1. `Proc Positive(i, k_1, k_2)`
2. \( v \leftarrow \text{node}(\text{select}_1(B, \pi^{-1}(i))) \)
3. \( v_c \leftarrow \text{anc}(v, \text{depth}(v) - 1) \)
4. \( v_1 \leftarrow \text{anc}((\text{leftmost}(v_c), 1)) \)
5. \( c \leftarrow \text{depth}(v_1) \)
6. \( v' \leftarrow \text{loa}(v_1, v) \)
7. \( d \leftarrow \text{depth}(v) - \text{depth}(v') \)
8. If \( k_1 < d \) then
   9. Compute path query from \( \text{anc}(v, k_1) \) to \( \text{anc}(v, \text{min}(k_2, d - 1)) \)
10. If \( k_2 \geq d \) then
    11. \( k_1' \leftarrow \text{max}(0, k_1 - d) \)
    12. \( k_2' \leftarrow k_2 - d \)
    13. If \( k_2' - k_1' \geq c - 1 \) then
        14. Compute path query from \( v_1 \) to \( v_c \)
    15. Else
        16. If \( k_1' < \text{depth}(v') \) then \( v_s \leftarrow \text{anc}(v', k_1') \)
        17. Else \( v_s \leftarrow \text{anc}(v_1, (k_1' - \text{depth}(v')) \mod c \)
        18. If \( k_2' < \text{depth}(v') \) then \( v_c \leftarrow \text{anc}(v', k_2') \)
        19. Else \( v_c \leftarrow \text{anc}(v_1, (k_2' - \text{depth}(v')) \mod c \)
        20. If \( \text{depth}(v_s) \geq \text{depth}(v_c) \) and \( \text{anc}(v_s, \text{depth}(v_s) - \text{depth}(v_c)) = v_c \) then
            21. Compute path query from \( v_s \) to \( v_c \)
        22. Else
            23. Compute path query from \( v_s \) to \( v_c \)
            24. Compute path query from \( v_1 \) to \( v_c \)
    25. Return the composition of all the path queries performed; resulting nodes are converted into domain values \( \pi(\text{rank}_1(B, \text{id}(u))) \)

The query from a node \( v'_i \). Since the wavelet tree has each distinct element mentioned once or twice, its entropy is essentially maximal, and we have the following results for this case.

- **Corollary 14.** Let \( f : [1..n] \rightarrow [1..n] \) be a function. Then there exists a data structure using \( n \lg n + o(n \lg n) \) bits that answers counting queries on the positive paths of \( f \) in time \( O((\lg n / \lg \lg n)) \), and also reports those \( r \) results in time \( O((r + 1)\lg n / \lg \lg n). \)

- **Corollary 15.** Let \( f : [1..n] \rightarrow [1..n] \) be a function. Then there exists a data structure using \( 2n \lg n + o(n \lg n) \) bits that answers selection queries on the positive paths of \( f \) in time \( O((\lg n / \lg \lg n)) \).

We can also simplify Corollary 10, where the structures used perform the equivalent to \textit{select} queries on the sequence of labels. Here, we can find where the domain value \( i \) appears in the sequence, and then map it to the tree using \( p \) and \( B \). Then there is no need for permutation \( \pi \), and we can subtract \( n \lg n \) bits to the space in this corollary.\(^3\)

\(^3\) The same happens in Corollary 9, but the query makes no sense if the labels are all unique.

Abstract
Given a string $S$ of length $n$, the classic string indexing problem is to preprocess $S$ into a compact
data structure that supports efficient subsequent pattern queries. In the deterministic variant the
goal is to solve the string indexing problem without any randomization (at preprocessing time or
query time). In the packed variant the strings are stored with several character in a single word,
giving us the opportunity to read multiple characters simultaneously. Our main result is a new
string index in the deterministic and packed setting. Given a packed string $S$ of length $n$ over
an alphabet $\sigma$, we show how to preprocess $S$ in $O(n)$ (deterministic) time and space $O(n)$
such that given a packed pattern string of length $m$ we can support queries in (deterministic) time
$O(m/\alpha + \log m + \log \log \sigma)$, where $\alpha = w/\log \sigma$ is the number of characters packed in a word of
size $w = \Theta(\log n)$. Our query time is always at least as good as the previous best known bounds
and whenever several characters are packed in a word, i.e., $\log \sigma \ll w$, the query times are faster.

1 Introduction

Let $S$ be a string of length $n$ over an alphabet of size $\sigma$. The string indexing problem is to
preprocess $S$ into a compact data structure that supports efficient subsequent pattern queries.
Typical queries include existential queries (decide if the pattern occurs in $S$), reporting
queries (return all positions where the pattern occurs), and counting queries (returning the
number of occurrences of the pattern).

The string indexing problem is a classic well-studied problem in combinatorial pattern
matching and the standard textbook solutions are the suffix tree and the suffix array (see
e.g., [9, 10, 11, 14]). A straightforward implementation of suffix trees leads to an $O(n)$
preprocessing time and space solution that given a pattern of length $m$ supports existential
and counting queries in time $O(m \log \sigma)$ and reporting queries in time $O(m \log \sigma + occ)$,
where occ is the number of occurrences of the pattern. The suffix array implemented with
additional arrays storing longest common prefixes leads to a solution that also uses $O(n)$
preprocessing time and space while supporting existential and counting queries in time

Deterministic Indexing for Packed Strings

$O(m + \log n)$ and reporting queries in time $O(m + \log n + \text{occ})$. If we instead combine suffix trees with perfect hashing \cite{7} we obtain $O(n)$ expected preprocessing time and $O(n)$ space, while supporting existential and counting queries in time $O(m)$ and reporting queries in time $O(m + \text{occ})$. The above bounds hold assuming that the alphabet size $\sigma$ is polynomial in $n$. If this is not the case, additional time for sorting the alphabet is required \cite{5}. For simplicity, we adopt this convention in all of the bounds throughout the paper.

In the deterministic variant the goal is to solve the string indexing problem without any randomization. In particular, we cannot combine suffix trees with perfect hashing to obtain $O(m)$ or $O(m + \text{occ})$ query times. In this setting Cole et al. \cite{4} showed how to combine the suffix tree and suffix array into the suffix tray that uses $O(n)$ preprocessing time and space and supports existential and counting queries in $O(m + \log \sigma)$ time and reporting queries in $O(m + \log \sigma + \text{occ})$ time. Recently, the query times were improved by Fischer and Gawrychowski \cite{6} to $O(m + \log \log \sigma)$ and $O(m + \log \log \sigma + \text{occ})$, respectively.

In the packed variant the strings are given in a packed representation, with several characters in a single word \cite{3, 2, 1, 13}. For instance, DNA-sequences have an alphabet of size 4 and are therefore typically stored using 2 bits per character with 32 characters in a 64-bit word. On packed strings we can read multiple characters in constant time and hence potentially do better than the immediate $\Omega(m)$ or $\Omega(m + \text{occ})$ lower bound for existential/counting queries and reporting queries, respectively. In this setting Takagi et al. \cite{13} recently introduced the packed compact trie that stores packed strings succinctly and also supports dynamic insertion and deletions of strings. In a static and deterministic setting their data structure implies a linear space and superlinear time preprocessing solution that uses $O(\frac{m\log n}{\alpha})$ and $O(\frac{m\log n + \text{occ}}{\alpha})$ query time, respectively.

In this paper, we consider the string indexing problem in the deterministic and packed setting simultaneously, and present a solution that improves all of the above bounds.

1.1 Setup and result

We assume a standard unit-cost word RAM with word length $w = \Theta(\log n)$, and a standard instruction set including arithmetic operations, bitwise boolean operations, and shifts. All strings in this paper are over an alphabet $\Sigma$ of size $\sigma$. The packed representation of a string $A$ is obtained by storing $\alpha = w/\log \sigma$ characters per word thus representing $A$ in $O(|A| \log \sigma/\alpha)$ words. If $A$ is given in the packed representation we simply say that $A$ is a packed string.

Throughout the paper let $S$ be a string of length $n$. Our goal is to preprocess $S$ into a compact data structure that given a packed pattern string $P$ supports the following queries.

- **Count($P$):** Return the number of occurrence of $P$ in $S$.
- **Locate($P$):** Report all occurrences of $P$ in $S$.
- **Predecessor($P$):** Returns the predecessor of $P$ in $S$, i.e., the lexicographically largest suffix in $S$ that is smaller than $P$.

We show the following main result.

**Theorem 1.** Let $S$ be a string of length $n$ over an alphabet of size $\sigma$ and let $\alpha = \frac{w}{\log \sigma}$ be the number of characters packed in a word. Given $S$ we can build an index in $O(n)$ deterministic time and space such that given a packed pattern string of length $m$ we can support **Count** and **Predecessor** in time $O(\frac{m\alpha}{\alpha} + \log m + \log \log \sigma)$ and **Locate** in time $O(\frac{m\alpha}{\alpha} + \log m + \log \log \sigma + \text{occ})$ time.

Compared to the result of Fischer and Gawrychowski \cite{6}, Thm 1 is always at least as good and whenever several characters are packed in a word, i.e., $\log \sigma \ll w$, the query times are faster. Compared to the result of Takagi et al. \cite{13}, our query time is a factor $\log \log n$ faster.
Technically, our results are obtained by a novel combination of previous techniques. Our general tree decomposition closely follows Fischer and Gawrychowski [6], but different ideas are needed to handle packed strings efficiently. We also show how to extend the classic suffix array search algorithm to handle packed strings efficiently.

2 Preliminaries

2.1 Deterministic hashing and predecessor

We use the following results on deterministic hashing and predecessor data structures.

► Lemma 2 (Ružič [12, Theorem 3]). A static linear space dictionary on a set of $k$ keys can be deterministically constructed in time $O(k (\log \log k)^2)$, so that lookups to the dictionary take time $O(1)$.

Fischer and Gawrychowski [6] use the same result for hashing characters. In our context we will apply it for hashing words of packed characters.

► Lemma 3 (Fischer and Gawrychowski [6, Proposition 7]). A static linear space predecessor data structure on a set of $k$ keys from a universe of size $u$ can be constructed deterministically in $O(k)$ time and $O(k)$ space such that predecessor queries can be answered deterministically in time $O(\log \log u)$.

2.2 Suffix tree

The suffix tree $T_S$ of $S$ is the compacted trie over the $n$ suffixes from the string $S$. We assume that the special character $\$ \not\in \Sigma$ is appended to every suffix of $S$ such that each string is ending in a leaf of the tree. The edges are sorted lexicographically from left to right. We say that a leaf represents the suffix that is spelled out by concatenating the labels of the edges on the path from the root to the leaf. For a node $v$ in $T_S$, we say that the subtree of $v$ is the tree induced by $v$ and all proper descendants of $v$. We distinguish between implicit and explicit nodes: implicit nodes are conceptual and refer to the original non branching nodes from the trie without compacted paths. Explicit nodes are the branching nodes in the original trie. When we refer to nodes that are not specified as either explicit or implicit, then we are always referring to explicit nodes. The lexicographic ordering of the suffixes represented by the leaves corresponds to the ordering of the leaves from left to right in the compacted trie. For navigating from node to child, each node has a predecessor data structure over the first characters of every edge going to a child. With the predecessor data structure from Lemma 3 navigation from node to child takes $O(\log \log \sigma)$ time and both the space and the construction time of the predecessor data structure is linear in the number of children.

2.3 Suffix array

Let $S_1, S_2, \ldots, S_n$ be the $n$ suffixes of $S$ from left to right. The suffix array $SA_S$ of $S$ gives the lexicographic ordering of the suffixes such that $SA_S[i]$ refers to the $i$th lexicographically largest suffix of $S$. This means that for every $1 < i \leq n$ we have that $SA_S[i-1]$ is lexicographically smaller than $SA_S[i]$. For simplicity we let $SA[i]$ refer to the suffix $SA_S[i]$ and we say that $SA_S[i]$ represents the suffix $SA[i]$. Every suffix from $S$ with pattern $P$ as a prefix will be located in a consecutive range of $SA_S$. This range corresponds to the range of consecutive leaves in the subtree spanned by the explicit or implicit node that represents $P$ in $T_S$. We can find the range of $SA_S$ where $P$ prefixes every suffix by performing binary search twice
over \(SA_S\). A naïve binary search takes \(O(m \log n)\) time: We maintain the boundaries, \(L\) and \(R\), of the current search interval and in each iteration we compare the median string from the range \(L\) to \(R\) in \(SA_S\), with \(P\), and update \(L\) and \(R\) accordingly. This can be improved to \(O(m + \log n)\) time if we have access to additional arrays storing the value of the longest common prefixes between a selection of strings from \(SA_S\). We construct the suffix array from the suffix tree in \(O(n)\) time.

### 3 Deterministic index for packed strings

In this section we describe how to construct and query our deterministic index for packed strings. This structure is the basis for our result in Thm 1. For short patterns where \(m < \log_\sigma n - 1\) we store tabulated data that enables us to answer queries fast. We construct the tables in \(O(n)\) time and space and answer queries in \(O(\log \log \sigma + \text{occ})\) time. For long patterns where \(m \geq \log_\sigma n - 1\) we use a combination of a suffix tree and a suffix array that we construct in \(O(n)\) time and space such that queries take \(O(m/\alpha + \log n + \text{occ})\) time. For \(m \geq \log_\sigma n - 1\) we have that \(\log \log n = \log \left(\frac{\log n}{\log \sigma}\right) = \log \log_\sigma n + \log \log \sigma \leq \log(\log_\sigma n - 1) + 1 + \log \log \sigma \leq \log m + 1 + \log \log \sigma\). This gives us a query time of \(O(m/\alpha + \log m + \log \log \sigma + \text{occ})\) for the deterministic packed index. We need the following connections between \(T_S\) and \(SA_S\): For each explicit node \(t\) in \(T_S\) we store a reference to the range of \(SA_S\) that corresponds to the leaves spanned by the subtree of \(t\) and for each index in \(SA_S\) we store a reference to the corresponding leaf in \(T_S\) that represents the same string.

We first describe our word accelerated algorithm for matching patterns in \(SA_S\) that we need for answering queries on long patterns. Then we describe how to build and use the data structures for answering queries on short and long patterns.

#### 3.1 Packed matching in \(SA_S\)

We now show how to word accelerate the suffix array matching algorithm by Manber and Myers [10]. They spend \(O(m)\) time reading \(P\) but by reading \(\alpha\) characters in constant time we can reduce this to \(O(m/\alpha)\). We let \(\text{LCP}(i,j)\) denote the length of the longest common prefix between the suffixes \(SA_S[i]\) and \(SA_S[j]\) and obtain the result in Lemma 4.

**Lemma 4.** Given the suffix array \(SA_S\) over the packed string \(S\) and a data structure for answering the relevant LCP queries, we can find the lexicographic predecessor of a packed pattern \(P\) of length \(m\) in \(SA_S\) in \(O(m/\alpha + \log n)\) time where \(\alpha\) is the number of characters we can pack in a word.

In the algorithm by Manber and Myers we maintain the left and right boundaries of the current search interval of \(SA_S\) denoted by \(L\) and \(R\) and the length of the longest common prefix between \(SA_S[L]\) and \(P\), and between \(SA_S[R]\) and \(P\), that we denote by \(l\) and \(r\), respectively. Initially the search interval is the whole range of \(SA_S\) such that \(L = 1\) and \(R = n\). In an iteration we do as follows: If \(l = r\) we start comparing \(SA_S[M]\) with \(P\) from index \(l + 1\) until we find a mismatch and update either \(L\) and \(l\), or \(R\) and \(r\), depending on whether \(SA_S[M]\) is lexicographically larger or smaller than \(P\). Otherwise, when \(l \neq r\), we perform an LCP query that enable us to either halve the range of \(SA_S\) without reading from \(P\) or start comparing \(SA_S[M]\) with \(P\) from index \(l + 1\) as in the \(l = r\) case. When \(l > r\) there are three cases: If \(\text{LCP}(L,M) > l\) then \(P\) is lexicographically larger than \(SA_S[M]\) and we set \(L\) to \(M\) and continue with the next iteration. If \(\text{LCP}(L,M) < l\) then \(P\) is lexicographically smaller than \(SA_S[M]\) and we set \(R\) to \(M\) and set \(r\) to \(\text{LCP}(L,M)\) and continue with the next iteration. If \(\text{LCP}(L,M) = l\) then we compare \(SA_S[M]\) and \(P\) from index \(l + 1\) until
we find a mismatch. Let that mismatch be at index \( l + i \). If the mismatch means that \( P \) is lexicographically smaller than \( S A_S[M] \) then we set \( R \) to \( M \) and set \( r \) to \( l + i - 1 \) and continue with the next iteration. If the mismatch means that \( P \) is lexicographically larger than \( S A_S[M] \) then we set \( L \) to \( M \) and set \( l \) to \( l + i - 1 \) and continue with the next iteration. Three symmetrical cases exists when \( r > l \).

We generalize their algorithm to work on word packed strings such that we can compare \( \alpha \) characters in constant time. In each iteration where we need to read from \( P \) we align the next \( \alpha \) characters from \( P \) and \( S A_S[M] \) such that we can compare them in constant time: Assume that we need to read the range from \( i \) to \( i + \alpha - 1 \) in \( P \). If this range of characters is contained in one word we do not need to align. Otherwise, we extract the relevant parts of the words that contain the range with bitwise shifts and combine them in \( w_{align} \) with a bitwise or. See Figure 1. We align the \( \alpha \) characters from \( S A_S[M] \) in the same way and store them in \( w'_{align} \).

![Figure 1](image)

Alignment of \( \alpha \) characters that extends over a word boundary where \( c' = c + 1 - \alpha \). The relevant part of the lower word \( w_1 \) and upper word \( w_2 \) is combined with bitwise shifts, a bitwise or and the \( g \) bits on the right is set to 0.

We use a bitwise exclusive or operation between \( w_{align} \) and \( w'_{align} \) to construct a word where the most significant set bit is at a bit position that belong to the mismatching character with the lowest index. We obtain the position of the most significant set bit in constant time with the technique of Fredman and Willard [8]. From this we know exactly how many of the next \( \alpha \) characters that match and we can increase \( i \) accordingly. Since every mismatch encountered result in a halving of the search range of \( S A_S \) we can never read more than \( O(\log n) \) incomplete chunks. The number of complete chunks we read is bounded by \( O(m/\alpha) \). Overall we obtain a \( O(m/\alpha + \log n) \) time algorithm for matching in \( S A_S \). This result is summarized in Lemma 4.

### 3.2 Handling short patterns

Now we show how to answer count, locate and lexicographic predecessor queries on short patterns. We store an array containing an index for every possible pattern \( P \) where \( m < \log_\alpha n - 1 \) and at the index we store a pointer to the deepest node in \( T_S \) that prefixes \( P \). We call this node \( d_P \). We use \( d_P \) as the basis for answering every query on short patterns. We assume that the range in \( S A_S \) spanned by \( d_P \) goes from \( l \) to \( r \). We answer predecessor queries as follows: If \( P \) is lexicographically smaller than \( S A_S[0] \) then \( P \) has no predecessor in \( S A_S \). Otherwise, we find the predecessor as follows: If \( d_P \) represents \( P \) then the predecessor of \( P \) is located at index \( l - 1 \) of \( S A_S \). Otherwise, we assume that \( d_P \) prefixes \( P \) with \( i \) characters and need to decide whether \( P \) continues on an edge out of \( d_P \) or \( P \) deviates from \( T_S \) in \( d_P \). We do this by querying the predecessor data structure over the children of \( d_P \) with the character at position \( i + 1 \) of \( P \). If this query does not return an edge, then \( P[i+1] \) is lexicographically
Deterministic Indexing for Packed Strings

We report the node in word that represents the string. We fill each of these indices with a pointer to we return the number of leaves spanned by

3.3 Handling long patterns

The first character of $e_{\text{pred}}$ is not identical to $P[i+1]$. Then the predecessor of $P$ is the lexicographically largest string in the subtree under $e_{\text{pred}}$.

Case 1: The first character of $e_{\text{pred}}$ is identical to $P[i+1]$. In this case, if there exists an edge $e_{\text{pred}}$ out of $d_P$ on the left side of $e_{\text{pred}}$, then the predecessor of $P$ is the lexicographically largest string in the subtree under $e'_{\text{pred}}$ and otherwise the predecessor is the string at index $l - 1$ of $SA_S$.

We report the node in $T_S$ that represents the predecessor of $P$.

We let $e_{\text{pred}}$ be defined as above and answer count queries as follows: If $d_P$ represents $P$ we return the number of leaves spanned by $d_P$ in $T_S$. If $P$ instead continues and ends on $e_{\text{pred}}$ we report the number of leaves spanned by the subtree below $e_{\text{pred}}$. We answer locate queries in the same way but instead of reporting the range we report the strings in the range.

We find $d_P$ in $O(1)$ time and $e_{\text{pred}}$ in $O(\log \log \sigma)$ time. In total we answer predecessor and count queries in $O(\log \log \sigma)$ time and locate queries in $O(\log \log \sigma + \text{occ})$ time.

Since $m < \log \sigma n - 1$ there exists $\sigma + \sigma^2 + \ldots + \sigma^{\lfloor \log \sigma n \rfloor} \leq \sigma^{\lfloor \log \sigma n \rfloor} \leq \sigma^{\log \sigma n} = n$ short patterns and we compute them in $O(n)$ time by performing a preorder traversal of $T_S$ bounded to depth $\log \sigma n - 1$. Let $d_P$ be the node we are currently visiting and let $d_{\text{next}}$ be the node we visit next. When we visit $d_P$ we fill the tabulation array for every string that is lexicographically larger than or equal to the string represented by $d_P$ and lexicographically smaller than the string represented by $d_{\text{next}}$. Every short string can be stored in a word of memory and therefore we can index the tabulation array with the numerical value of the word that represents the string. We fill each of these indices with a pointer to $d_P$ since $d_P$ is the deepest node in $T_S$ that represents a string that prefixes these strings. We can store the tabulation array in $O(n)$ space.

3.3 Handling long patterns

Now we show how to answer count, locate and lexicographic predecessor queries on long patterns. We first give an overview of our solution followed by a detailed description of the individual parts. In $T_S$ we distinguish between light and heavy nodes. If a subtree under a node spans at least $\log^2 \log n$ leaves, we call the node heavy, otherwise we call it light. A node is a heavy branching node if it has at least two heavy children and all the heavy nodes constitute a subtree that we call the heavy tree. We decompose the heavy tree into micro trees of height $\alpha$ and we augment every micro tree with a data structure that enables navigation from root to leaf in constant time. For micro trees containing a heavy branching node we do this with deterministic hashing and for micro trees without a heavy branching node we just compare the relevant part of $P$ with the one unique path of the heavy tree that goes through the micro tree. To avoid navigating the light nodes we in each light node store a pointer to the range of $SA_S$ that the node spans. We construct two predecessor data structures for each micro tree: The light predecessor structure over the strings represented by the light nodes that are connected to the heavy nodes in the micro tree and the heavy predecessor structure over the heavy nodes in the micro tree. We answer queries on $P$ as follows: We traverse the heavy tree in chunks of $\alpha$ characters until we are unable to traverse a complete micro tree. This means that $P$ either continues in a light node, ends in the micro tree or deviates from $T_S$ in the micro tree. We can decide if $P$ continues in a light node with the light predecessor structure and if this is the case we answer the query with the packed matching algorithm on the range of $SA_S$ spanned by the light node. Otherwise, we use the heavy predecessor structure for finding $d_P$ in the micro tree and use $d_P$ for answering the
The decomposition of $HT_S$ in micro trees of height $\alpha$. One micro tree is shown with the root at string depth $\alpha$ and the boundary nodes at string depth $2\alpha$.

query as in section 3.2. The following sections describes in more detail how we build our data structure and answer queries.

### 3.3.1 Data structure

This section describes our data structure in details. If a subtree under a node in $T_S$ spans at least $\log^2 \log n$ leaves, we call the node heavy. The heavy tree $HT_S$ is the induced subgraph of all the the heavy nodes in $T_S$. We decompose $HT_S$ into micro trees of string depth $\alpha$. This decomposition into micro trees of height $\alpha$ was also employed by Takagi et al. [13]. A node, explicit or implicit, is a boundary node if its string depth is a multiple of $\alpha$. Except for the original root and leaves of $HT_S$, each boundary node belongs to two micro trees i.e., a boundary node at depth $d\alpha$ is the root in a micro tree that starts at string depth $d\alpha$ and is a leaf in a micro tree that starts at string depth $(d - 1)\alpha$. Figure 2 shows the decomposition of $HT_S$ into micro trees of string depth $\alpha$.

We augment every micro tree with information that enables us to navigate from root to leaf in constant time. To avoid using too much space we promote only some of the implicit boundary nodes to explicit nodes. We distinguish between three kinds of micro trees:

- **Type 1.** At least one heavy branching node exists in the micro tree: We promote the root and leaves to explicit nodes and use deterministic hashing to navigate the micro tree from root to leaf. Because the micro tree is of height $\alpha$, each of the strings represented by the leaves in the micro tree fits in a word and can be used as a key for hashing. We say that the root is a hashing node and the leaves are hashed nodes. We will postpone the analysis of time and space used by the micro trees that use hashing for navigation.

- **Type 2.** No heavy branching node exists in the micro tree: When the micro tree does not contain a heavy branching node, the micro tree is simply a path from root to leaf. Here we distinguish between two cases:
  
  - **Type 2a.** The micro tree contains an explicit non branching heavy node: We promote the root and leaf to explicit nodes. Navigating from root to leaf takes constant time by comparing the string represented by the leaf with the appropriate part of $P$. We charge the space increase from the promotion of the root and leaf to the explicit non branching heavy node. Since there are at most $n$ explicit non branching heavy nodes we never promote more than $2n$ implicit nodes from type 2a micro trees.
Type 2b. The micro tree does not contain an explicit heavy node: Let $t$ be a micro tree with no explicit heavy nodes. If the root of $t$ is a leaf in a micro tree that contains an explicit heavy node, we promote the root of $t$ to an explicit node and store a pointer to the root of the nearest micro tree below $t$ that contains an explicit heavy node. The path from root to root corresponds to a substring in $S$ that we navigate by comparing this string to the appropriate part of $P$. We charge the space increase from the promotion of the root to the heavy node descendant. Since we have at most $n$ explicit heavy nodes we promote no more than $n$ implicit nodes from type 2b micro trees. If the root of $t$ is a leaf in a micro tree without an explicit heavy node we do not promote the root of $t$.

We say that a node in $T_S$ is a heavy leaf if it is a heavy node with no heavy children. We want to bound the number of heavy branching nodes and heavy leaves. Every heavy leaf spans at least $\log^2 \log n$ leaves of $T_S$. This means we can have at most $n/\log^2 \log n$ heavy leaves in $T_S$. Since we have at most one branching heavy node per heavy leaf the number of heavy branching nodes is at most $n/\log^2 \log n$.

We want to bound the number of implicit nodes that are promoted to explicit hashed nodes. This number is critical for constructing all hash functions in $O(n)$ time. We bound the number of promoted hashed nodes by associating each with the nearest descendant that is either a heavy branching node or a heavy leaf: Let $l$ be a promoted hashed node in a micro tree that contain a heavy branching node $h$. Then every promoted hashed node above $l$ is associated with $h$ or a node above $h$ in the tree. Hence, no other promoted node can be associated with the first encountered heavy branching or leaf node below $l$. Since we have at most $O(n/\log^2 \log n)$ heavy branching and heavy leaf nodes we also have at most $O(n/\log^2 \log n)$ implicit nodes that are promoted to explicit hashed nodes.

With deterministic hashing from Lemma 2 the total time for constructing the explicit hashing nodes are given as follows. Here $H$ is the set of all the hash functions and we bound the elements in every hash function $h$ to $n/\log^2 \log n$.

$$O \left( \sum_{h \in H} |h| \log^2 \log |h| \right) = O \left( \sum_{h \in H} |h| \log^2 \log(n/\log^2 \log n) \right)$$

$$= O \left( \log^2 \log(n/\log^2 \log n) \cdot \sum_{h \in H} |h| \right) = O \left( \log^2 \log(n/\log^2 \log n) \frac{n}{\log^2 \log n} \right) = O(n)$$

Summing the elements of every hash function is bounded by the maximum number of promoted nodes, i.e. $O(n/\log^2 \log n)$. To conclude, we spend linear time constructing the hash functions in the micro trees that contain a heavy branching node.

We associate two predecessor data structures with each micro tree that contains a heavy node: The first predecessor structure contains every light node that is a child of a heavy node in the micro tree. We call this predecessor data structure for the light predecessor structure of the micro tree. The key for each light node is the string on the path from the root of the micro tree to the node itself padded with character $\$ $ such that every string has length $\alpha$. These keys are ordered lexicographically in the predecessor data structure and a successful query yields a pointer to the node. The second predecessor structure is similar to the first but contains every heavy node in the micro tree. We call this predecessor structure for the heavy predecessor structure. We use Lemma 3 for the predecessor structures. The total size of every light and heavy predecessor structures is $O(n)$ and a query in both takes $O(\log \log n)$ because the universe is of size $(\sigma + 1)^\alpha$. 
For each light node that are a child of a heavy node we additionally store pointers to the range of \( S_A \) that corresponds to the leaves in \( T_S \) that the light node spans.

### 3.3.2 Answering queries

We answer queries on long patterns as follows. First we search for the deepest micro tree in \( H_T \) where the root prefixes \( P \). We do this by navigating the heavy tree in chunks of \( \alpha \) characters starting from the root. Assuming that we have already matched a prefix of \( P \) consisting of \( i \) chunks of \( \alpha \) characters we need to show how to match the \((i+1)\)th chunk: If the micro tree is of type 1 and \( P \) has length at least \((i+1)\alpha\), we try to hash the substring \( P[i\alpha,(i+1)\alpha] \). If we obtain a node \( v \) from the hash function we continue matching chunk \( P[(i+1)\alpha,(i+2)\alpha] \) from \( v \). If the micro tree is of type 2 we compare \( \alpha \) sized chunks of \( P \) with the string on the unique path from root to the first micro tree with an explicit root and continue matching from here. We have found the deepest micro tree where the root prefixes \( P \) when we are unable to match a complete chunk of \( \alpha \) characters or are unable to reach a micro tree with an explicit root. From this micro tree we need to decide whether the query is answered by searching \( S_A \) from a light node or answered by finding \( d_P \) in the micro tree, where \( d_P \) is defined as in Section 3.2, i.e. the deepest node in \( T_S \) that prefixes \( P \). We check if \( P \) continues in a light node by querying the light predecessor structure of the micro tree with the next unmatched \( \alpha \) characters from \( P \) and pad with character \$ if less than \( \alpha \) characters remain unmatched in \( P \). If the light node returned by the query represents a string that prefixes \( P \) we answer the query by searching the range of \( S_A \) spanned by the light node with the packed matching algorithm.

When \( P \) does not continue in a light node we instead find and use \( d_P \) for answering the query: If the micro tree is of type 2b or the root of the micro tree represents \( P \) then \( d_P \) is the root of the micro tree. Otherwise, we find \( d_P \) with a technique, very similar to a technique used by Fredman and Willard [8], that queries the heavy predecessor structure three times as follows: We call the remaining part of \( P \), padded to length \( \alpha \) with character \$, for \( p_0 \). We first query the predecessor structure with \( p_0 \) which yields a node that represents a string \( n_0 \). We then construct a string, \( p_1 \), that consists of the longest common prefix of \( p_0 \) and \( n_0 \), and as above, padded to length \( \alpha \). We query the predecessor structure with \( p_1 \) which yields a new node that represents a string \( n_1 \). We then construct a string, \( p_2 \), that consists of the longest common prefix of \( p_0 \) and \( n_1 \), again padded to length \( \alpha \). At last, we query the predecessor structure with \( p_2 \) which returns \( d_P \). Given \( d_P \), we answer count, locate and lexicographic predecessor queries exactly as we did in Section 3.2.

Now we prove the correctness of our queries. First we prove that if \( P \) continues in a light node then the query in the light predecessor structure returns that light node: Assume that \( P \) goes through the light node \( l_P \) that has a heavy parent in the micro tree \( T_p \) and that we query the light predecessor structure with the string \( Q_\alpha \). Let \( L_{\text{pred}} \) be the string that represents \( l_P \) in the light predecessor structure. Since \( P \) goes through \( l_P \) then \( L_{\text{pred}} \) is identical or lexicographically smaller than \( Q_\alpha \). Let \( L'_{\text{pred}} \) be the successor of \( L_{\text{pred}} \) in the light predecessor structure. Since \( L_{\text{pred}} \) is lexicographically smaller than \( L'_{\text{pred}} \) and has a longer common prefix with \( Q_\alpha \) than \( L'_{\text{pred}} \) has with \( Q_\alpha \), then \( L'_{\text{pred}} \) must be lexicographically larger than \( Q_\alpha \). Since \( Q_\alpha \) is identical or lexicographically larger than \( L_{\text{pred}} \) and lexicographically smaller than \( L'_{\text{pred}} \), a query on \( Q_\alpha \) in the light predecessor structure will return \( l_P \).

We now prove that the queries in the heavy predecessor structure always returns \( d_P \): Because \( P \) is not prefixed by a leaf of the micro tree or a light node from the light predecessor structure we know that \( d_P \) is a heavy node in the micro trie. In Figure 3, \( d_P \) is depicted and \( P \) either ends on or deviates from the edge \( e \) that leads to the tree \( T_2 \). The trees \( T_1 \),
Figure 3 Searching for a prefix of \( P \) in \( HT_s \).

\( T_2 \) and \( T_3 \) combined with \( d_P \) and the edge \( e \) constitute the subtree of \( d_P \). If \( P \) deviates to the left or ends on \( e \) then \( P \) is lexicographically smaller than every string represented in \( T_2 \). If \( P \) deviates to the right then \( P \) is lexicographically larger than every string represented in \( T_2 \). Assume that \( P \) deviates to the right on \( e \). Then the query to the heavy predecessor structure with pattern \( p_0 \) will yield \( n_0 \) that represents the lexicographically largest string in \( T_2 \). If \( P \) deviates to the right on \( e \) then \( P \) is lexicographically larger than every string represented in \( T_2 \). Assume that \( P \) deviates to the right on \( e \). Then the query to the heavy predecessor structure with pattern \( p_0 \) will yield \( n_0 \) that represents the lexicographically largest string in \( T_2 \). The pattern \( p_1 \) will then be represented by the implicit node from where \( P \) deviates from \( e \). The pattern \( p_1 \) is lexicographically smaller than every string represented in \( T_2 \) and a query will yield \( n_2 \) as the lexicographically largest node in \( T_1 \) or, if \( T_1 \) is empty, the node \( d_P \). Either way, the query on \( p_2 \) will yield the node \( d_P \). We can make similar arguments for the other cases where \( P \) ends on \( e \), deviates left from \( e \), ends at \( d_P \) or goes through \( d_P \) without following \( e \).

The following gives an analysis of the running time of our queries. We spend at most \( O(m/\alpha) \) time traversing the heavy tree. Both predecessor structures contains strings over a universe of size \( n \) such that a query takes \( O(\log \log n) \) time using Lemma 3. Each light node spans at most \( \log^2 \log n \) leaves which corresponds to an interval of length \( \log^2 \log n \) in \( SA_S \) that we search in \( O(m/\alpha + \log \log \log n) \) time with the word accelerated algorithm for matching in \( SA_S \). Overall, we spend \( O(m/\alpha + \log \log n) \) time for answering count and lexicographic predecessor queries and \( O(m/\alpha + \log \log n + \text{occ}) \) time for answering locate queries. Since we only query this data structure for patterns where \( m \geq \log_\sigma n - 1 \) we have that \( \log \log n = \log(\log \log n) \) \( \log \sigma = \log \log_\sigma n + \log \log(\sigma) \leq \log(\log_\sigma n - 1) + 1 + \log \log(\sigma) \leq \log(m) + 1 + \log \log(\sigma) \), such that we answer count and lexicographic predecessor queries in \( O(m/\alpha + \log m + \log \log \sigma) \) time and locate queries in \( O(m/\alpha + \log m + \log \log \sigma + \text{occ}) \) time. Combined with our solution for patterns where \( m < \log_\sigma n - 1 \), that answer the queries in \( O(\log \log \sigma) \) and \( O(\log \log \sigma + \text{occ}) \) time, respectively, we can for patterns of any length answer count and lexicographic predecessor queries in \( O(m/\alpha + \log m + \log \log \sigma) \) time and locate queries in \( O(m/\alpha + \log m + \log \log \sigma + \text{occ}) \) time. This is our main result which is summarized in Thm 1.

Representing the Suffix Tree with the CDAWG

Djamal Belazzougui and Fabio Cunial

Abstract

Given a string $T$, it is known that its suffix tree can be represented using the compact directed acyclic word graph (CDAWG) with $e_T$ arcs, taking overall $O(e_T + e_T)$ words of space, where $\overline{T}$ is the reverse of $T$, and supporting some key operations in time between $O(1)$ and $O(\log \log n)$ in the worst case. This representation is especially appealing for highly repetitive strings, like collections of similar genomes or of version-controlled documents, in which $e_T$ grows sublinearly in the length of $T$ in practice. In this paper we augment such representation, supporting a number of additional queries in worst-case time between $O(1)$ and $O(\log n)$ in the RAM model, without increasing space complexity asymptotically. Our technique, based on a heavy path decomposition of the suffix tree, enables also a representation of the suffix array, of the inverse suffix array, and of $T$ itself, that takes $O(e_T)$ words of space, and that supports random access in $O(\log n)$ time. Furthermore, we establish a connection between the reversed CDAWG of $T$ and a context-free grammar that produces $T$ and only $T$, which might have independent interest.

1 Introduction

Given a string $T$ of length $n$, the compressed suffix tree [21, 18] and the compressed suffix array can take an amount of space that is bounded by the $k$-th order empirical entropy of $T$, but such measure of redundancy is known not to be meaningful when $T$ is very repetitive [11], e.g. a collection of similar genomes. The space taken by such compressed data structures also includes a $o(n)$ term, typically $O(n/\text{polylog}(n))$, which can become an obstacle when $T$ is very compressible. Rather than compressing the suffix array, we could compress a differentially encoded suffix array [12], which stores at every position the difference between two consecutive positions of the suffix array. Previous approaches have compressed such differential array using grammar or Lempel-Ziv compression [12], and the same methods can be used to compress the suffix tree topology and the LCP array [1, 17]. Such heuristics, however, have either no theoretical guarantee on their performance [1, 17], or weak ones [12].

In previous research [4] we described a representation of the suffix tree of $T$ that takes space proportional to the size of the compact directed acyclic word graph (CDAWG) of $T$, and that supports a number of operations in time between $O(1)$ and $O(\log \log n)$ in the worst case (see Table 2). If $T$ is highly repetitive, the size of the CDAWG of $T$ is known to grow...

sublinearly in the length of $T$ in practice (see e.g. [4]). Being related to maximal repeats, the size of the CDAWG is also a natural measure of redundancy for very repetitive strings. Moreover, since the difference between consecutive suffix array positions is the same inside isomorphic subtrees of the suffix tree, and since such isomorphic subtrees are compressed by the CDAWG, the CDAWG itself can be seen as a grammar that produces the differential suffix array, and the suffix tree can be seen as the parse tree of such grammar: this provides a formal substrate to heuristics that grammar-compress the differential suffix array.

In this paper we further exploit the compression of isomorphic subtrees of a suffix tree induced by the CDAWG, augmenting the representation of the suffix tree described in [4] with a number of additional operations that take between $O(1)$ and $O(\log n)$ time in the worst case (see Table 1), without increasing space complexity asymptotically. We also describe CDAWG-based representations of the suffix array, of the inverse suffix array, of the LCP array, and of $T$ itself, with $O(\log n)$ random access time.

Our approach is related to the work of Bille et al [7], in which a straight-line program (effectively a DAG) that produces the balanced parentheses representation of a tree with $n$ nodes, is used to support operations on the topology of the tree in $O(\log n)$ time. Applying such compression to the suffix tree achieves the space bounds of this paper, but it only supports operations on the topology of the tree, and it supports each operation in $O(\log n)$ time, whereas we achieve either constant or $O(\log \log n)$ time for some key primitives.

2 Preliminaries

We work in the RAM model with word length at least $\log n$ bits, where $n$ is the length of a string that is implicit from the context, and we index strings and arrays starting from one.

2.1 Graphs

We assume the reader to be familiar with the notions of tree and of directed acyclic graph (DAG). By $lca(u, v)$ we denote the lowest common ancestor of nodes $u$ and $v$ in a tree. By weighted tree we mean a tree with nonnegative weights on the edges, and we use $\omega(u, v)$ to denote the weight of edge $(u, v)$. Weighted DAGs are defined similarly. In this paper we only
deal with ordered trees and DAGs, in which there is a total order among the out-neighbors of every node. The $i$-th leaf of a tree is its $i$-th leaf in depth-first order, and to every node $v$ of a tree we assign the compact interval $[\text{sp}(v) \ldots \text{ep}(v)]$, in depth-first order, of all leaves that belong to the subtree rooted at $v$. In this paper we use the expression DAG also for directed acyclic multigraphs, allowing distinct arcs to have the same source and destination nodes. In what follows we consider just DAGs with exactly one source and one sink.

We denote by $T(G)$ the tree generated by DAG $G$ with the following recursive procedure: the tree generated by the sink of $G$ consists of a single node; the tree generated by a node $v$ of $G$ that is not the sink, consists of a node whose children are the roots of the subtrees generated by the out-neighbors of $v$ in $G$, taken in order, and connected to their parent by edges whose weight, if any, is identical to the weight of the corresponding arc of $G$. Note that: (1) every node of $T(G)$ is generated by exactly one node of $G$; (2) a node of $G$ different from the sink generates one or more internal nodes of $T(G)$, and the subtrees of $T(G)$ rooted at all such nodes are isomorphic; (3) the sink of $G$ can generate one or more leaves of $T(G)$; (4) there is a bijection, between the set of root-to-leaf paths in $T(G)$ and the set of source-to-sink paths in $G$, such that every path $v_1, \ldots, v_k$ in $T(G)$ is mapped to a path $v'_1, \ldots, v'_k$ in $G$, and such that $\omega(v_i, v_{i+1}) = \omega(v'_i, v'_{i+1})$ for all $i \in [1..k-1]$ if $T(G)$ is weighted. Symmetrically, given any tree $T$, merging all subtrees with identical topology and edge weights produces a DAG $G$ such that $T(G) = T$: we denote such DAG by $G(T)$. Clearly $G(T(G)) = G$.

Given nodes $v$ and $w$ of $T(G)$ such that $v$ is an ancestor of $w$, let $\text{nLeaves}(v)$ be the number of leaves in the subtree rooted at $v$, and let $\text{left}(v, w)$ (respectively, $\text{right}(v, w)$) be the number of leaves in the subtree rooted at $v$ that precede (respectively, follow) in depth-first order the leaves in the subtree rooted at $w$. A heavy path decomposition of $T(G)$ [14] is the following marking: for every node $u$, we mark exactly one edge $(u, v)$ as heavy if $\text{nLeaves}(v)$ is the largest among all children of $u$, with ties broken arbitrarily (Figure 1a). We call light an edge that is not heavy, and we call heavy path a maximal sequence of nodes $v_1, \ldots, v_k$ such that $(v_i, v_{i+1})$ is heavy for all $i \in [1..k-1]$. Note that $v_k$ is a leaf, every node of $T(G)$ belongs to exactly one heavy path, distinct heavy paths are connected by light edges, and every path from the root to a leaf contains $O(\log N)$ light edges, or equivalently intersects $O(\log N)$ heavy paths, where $N$ is the number of leaves of $T(G)$. Heavy paths are disjoint in $T(G)$, but their corresponding paths in $G$ form a spanning tree $\tau(G)$, with $O(n)$ nodes and edges, rooted at the sink of $G$, where $n$ is the number of nodes of $G$ (Figure 1b).

2.2 Strings

Let $\Sigma = [1..\sigma]$ be an integer alphabet, let $\# = 0 \notin \Sigma$ be a separator, and let $T \in [1..\sigma]^{n-1}\#$ be a string. Given a string $W \in [1..\sigma]^k$, we call the reverse of $W$ the string $\overline{W}$ obtained by reading $W$ from right to left. For a string $W \in [1..\sigma]^k\#$ we abuse notation, and we denote by $\overline{W}$ the string $\overline{W}[1..k]\#$. Given a substring $W$ of $T$, let $\mathcal{P}_T(W)$ be the set of all starting positions of $W$ in the circular version of $T$. A repeat $W$ is a string that satisfies $|\mathcal{P}_T(W)| > 1$. We denote by $\Sigma^*_T(W)$ the set of characters $\{a \in [0..\sigma] : |\mathcal{P}_T(aW)| > 0\}$ and by $\Sigma^*_T(W)$ the set of characters $\{b \in [0..\sigma] : |\mathcal{P}_T(Wb)| > 0\}$. A repeat $W$ is right-maximal (respectively, left-maximal) iff $|\mathcal{P}_T(W)| > 1$ (respectively, iff $|\Sigma^*_T(W)| > 1$). It is well known that $T$ can have at most $n-1$ right-maximal repeats and at most $n-1$ left-maximal repeats. A maximal repeat of $T$ is a repeat that is both left- and right-maximal. It is also well known that a maximal repeat $W \in [1..\sigma]^m$ of $T$ is the equivalence class of all the right-maximal strings $[W[1..m], \ldots, W[k..m]]$ such that $W[k+1..m]$ is left-maximal, and $W[i..m]$ is not left-maximal for all $i \in [2..k]$.

For reasons of space we assume the reader to be familiar with the notion of suffix tree $\text{ST}_T$ of $T$ (see e.g. [13] for an introduction), which we do not define here. We denote by $\ell(\gamma)$,
or equivalently by $\ell(u, v)$, the string label of edge $\gamma = (u, v) \in E$, and we denote by $\ell(v)$ the string label of node $v \in V$. It is well known that a substring $W$ of $T$ is right-maximal iff $W = \ell(v)$ for some internal node $v$ of the suffix tree. We assume the reader to be familiar with the notion of suffix link connecting a node $v$ with $\ell(v) = aW$ for some $a \in [0..\sigma]$ to a node $w$ with $\ell(w) = W$. Here we just recall that inverting the direction of all suffix links yields the so-called explicit Weiner links.

Finally, we assume the reader to be familiar with the notion and uses of the Burrows-Wheeler transform of $T$ (see e.g. [10]). In this paper we use $\text{BWT}_T$ to denote the BWT of $T$, and we use $\text{range}(W) = [\text{sp}(W) \ldots \text{ep}(W)]$ to denote the lexicographic interval of a string $W$ in a BWT that is implicit from the context. As customary, we denote by $C[0..\sigma]$ the array such that $C[a]$ equals the number of occurrences of characters lexicographically smaller than $a$ in $T$. For a node $v$ of $\text{ST}_T$, we use the shortcut $\text{range}(v) = [\text{sp}(v) \ldots \text{ep}(v)]$ to denote $\text{range}(\ell(v))$. We say that $\text{BWT}_T[i..j]$ is a run iff $\text{BWT}_T[k] = c \in [0..\sigma]$ for all $k \in [i..j]$, and moreover if any substring $\text{BWT}_T[i'..j']$ such that $i' \leq i$, $j' \geq j$, and either $i' \neq i$ or $j' \neq j$, contains at least two distinct characters. We denote by $\mathcal{R}_T$ the set of all triplets $(i, j, c)$ such that $\text{BWT}_T[i..j]$ is a run of character $c$. Given a string $T \in [1..\sigma]^{n-1}$, we call run-length encoded $\text{BWT}$ (RLBWT) any representation of $\text{BWT}_T$ that takes $O(|\mathcal{R}_T|)$ words of space, and that supports the well known rank and select operations: see for example [15, 16, 23]. It is easy to implement a version of RLBWT that supports rank in $O(\log \log n)$ time and select in $O(\log \log n)$ time [4].

## 2.3 CDAWG

The compact directed acyclic word graph of a string $T$ (denoted by $\text{CDAWG}_T$ in what follows) is the minimal compact automaton that recognizes the suffixes of $T$ [8, 9]. We denote by $c_T$ the number of arcs in $\text{CDAWG}_T$. The CDAWG of $T$ can be seen as the minimization of $\text{ST}_T$, in which all leaves are merged to the same node (the sink) that represents $T$ itself, and in which all nodes except the sink are in one-to-one correspondence with the maximal repeats of $T$ [20]. Every arc of $\text{CDAWG}_T$ is labeled by a substring of $T$, and the out-neighbors $w_1, \ldots, w_k$ of every node $v$ of $\text{CDAWG}_T$ are sorted according to the lexicographic order of the distinct labels of arcs $(v, w_1), \ldots, (v, w_k)$. Since there is a bijection between the nodes of $\text{CDAWG}_T$ and the maximal repeats of $T$, the node $v'$ of $\text{CDAWG}_T$ with $\ell(v') = W$ is the equivalence class of the nodes $(v_1, \ldots, v_k)$ of $\text{ST}_T$ such that $\ell(v_i) = W[i..|W|]$ for all $i \in [1..k]$, and such that $v_k, v_{k-1}, \ldots, v_1$ is a maximal unary path of explicit Weiner links. The subtrees of $\text{ST}_T$ rooted at all such nodes are isomorphic, and $T(\text{CDAWG}_T) = \text{ST}_T$ (Figure 1b). It follows that the set of right-maximal strings that belong to the equivalence class of a maximal repeat can be represented by a single integer $k$, and a right-maximal string can be identified by the maximal repeat $W$ it belongs to, and by the length of the corresponding suffix of $W$. Similarly, a suffix of $T$ can be identified by a length relative to the sink of $\text{CDAWG}_T$.

In $\text{BWT}_T$, the right-maximal strings in the same equivalence class of a maximal repeat enjoy the following properties:

**Property 1** [4]. Let $\{W[1..m], \ldots, W[k..m]\}$ be the right-maximal strings that belong to the equivalence class of maximal repeat $W \in [1..\sigma]^m$ of a string $T$, and let $\text{range}(W[i..m]) = [p_i..q_i]$ for $i \in [1..k]$. Then: (1) $q_i - p_i + 1 = |q_j - p_j + 1|$ for all $i$ and $j$ in $[1..k]$; (2) $\text{BWT}_T[p_i..q_i] = W[i-1]|W| - p_i + 1$ for $i \in [2..k]$. Conversely, $\text{BWT}_T[p_1..q_k]$ contains at least two distinct characters. (3) $p_{i+1} = C[c] + \text{rank}_c(\text{BWT}_T, p_1)$ and $q_{i+1} = p_{i+1} + q_i - p_i$ for $i \in [2..k]$, where $c = W[i-1] = \text{BWT}_T[p_i]$. (4) $p_{i+1} = \text{select}_c(\text{BWT}_T, p_i - C[c])$ and
Figure 1 The data structures used in this paper for string $T = AGAGCGAGAGCGCGC\#$. (a) The suffix tree of $T$. Edges to leaves are labelled by just the first character of their string. The weight of edge $(u, v)$ is $sp(v) - sp(u)$. Heavy edges according to the number of leaves are bold. (b) The CDAWG of $T$. Just the first character of each arc label is shown. Arc weights are from (a). Arcs in the spanning tree $\tau$ are bold. (c) The reverse CDAWG. Arc $(u, v)$ is labelled by pair $(x, y)$, where $x$ is the order of $v$ among the out-neighbors of $u$, and $y$ is the weight in (b). (d) The compacted version of (c). (e) The weighted tree generated from (d), and the corresponding grammar.

$q_{i+1} = p_{i+1} + q_i - p_i$ for $i \in [1..k-1]$, where $c = W[i]$ is the character that satisfies $C[c] < p_i \leq C[c+1]$. (5) Let $c \in [0..\sigma]$, and let $\text{range}(W[i..m]) = [x_i..y_i]$ for $i \in [1..k]$. Then, $x_i = p_i + x_1 - p_1$ and $y_i = p_i + y_1 - p_1$.

Character $c$ in Property 1.4 can be computed in $O(\log \log n)$ time using a predecessor data structure that uses $O(\sigma)$ words of space [26]. Moreover, the equivalence class of a maximal repeat is related to the equivalence classes of its in-neighbors in the CDAWG in the following way:

**Property 2 ([4]).** Let $w$ be a node in $\text{CDAWG}_T$ with $\ell(w) = W \in [1..\sigma]^m$, and let $S_w = \{W[1..m], \ldots, W[k..m]\}$ be the right-maximal strings that belong to the equivalence class of node $w$. Let $\{v^1, \ldots, v^t\}$ be the in-neighbors of $w$ in $\text{CDAWG}_T$, and let $\{V^1, \ldots, V^t\}$ be their labels. Then, $S_w$ is partitioned into $t$ disjoint sets $S^1_w, \ldots, S^t_w$ such that $S^i_w = \{W[x^i+1..m], W[x^i+2..m], \ldots, W[x^i+|S_{v^i}[..m]|]\}$, and the right-maximal string $V^i[p..|V^i|]$ labels the parent of the locus of the right-maximal string $W[x^i+p-1..m]$ in $\text{ST}_T$.

Property 2 applied to the sink $v$ of $\text{CDAWG}_T$ partitions $T$ into $x$ left-maximal factors, where $x$ is the number of in-neighbors of $v$ (Figure 1e). Moreover, by Property 2, it is natural to say that in-neighbor $v^i$ of node $w$ is smaller than in-neighbor $v^j$ of node $w$ if $x^i < x^j$, or equivalently if the strings in $S^i_w$ are longer than the strings in $S^j_w$. We call $\text{CDAWG}_T$ the ordered DAG obtained by applying this order to the reverse of $\text{CDAWG}_T$, i.e. to the DAG
obtained by inverting the direction of all arcs of CDAWG_T (Figure 1c). Note that CDAWG_T is not the same as CDAWG_T, although there is a bijection between their sets of nodes. Note also that some nodes of CDAWG_T can have just one out-neighbor: for brevity we denote by CDAWG_T the graph obtained by collapsing every such node v, i.e. by adding the weight (if any) of the only outgoing arc from v to the weights of all incoming arcs to v, and by redirecting such incoming arcs to the out-neighbor of v (Figure 1d). This can be done in linear time by an inverse topological sort of CDAWG_T that starts from its sink.

The source of CDAWG_T is the sink of CDAWG_T, which is the equivalence class of all suffixes of T in string order, and there is a bijection between the distinct paths of CDAWG_T and the suffixes of T. It follows that:

► Property 3. The i-th leaf of T(CDAWG_T) in depth-first order corresponds to the i-th suffix of T in string order.

Thus, T(CDAWG_T) can be seen as the parse tree of a context-free grammar that generates T and only T, and CDAWG_T can be seen as such grammar (Figure 1e). This implies a lower bound on the size of the CDAWG:

► Lemma 1. Let f be the function that maps the length of a string to the size of its CDAWG, and let g be the function that maps the length of a string T to the size of the smallest grammar that produces T and only T. Then, f ∈ Ω(g).

In some classes of strings the size of the CDAWG is asymptotically the same as the size of the smallest grammar that produces the string, but in other classes the ratio between the two sizes reaches its maximum, O(n/ log n): see Section 2.1 in [4].

Let G be an ordered DAG, let γ = (v, w) be an edge of T(G), and assume that we assign to γ a weight equal to the offset sp(w) − sp(v) between the first leaf in the leaf interval of w and the first leaf in the leaf interval of v (Figure 1a). Thus, we can compute the depth-first order of a leaf of T(G) by summing the weights of all edges in its root-to-leaf path. Note that edges (v, w) and (v′, w′) in T such that v and v′ correspond to the same node v″ in G, and such that w and w′ correspond to the same node w″ in G, have the same weight: in the case of CDAWG_T and ST_T, this is equivalent to Property 1.5, and weights are offsets between the starting positions of nested BWT intervals (Figure 1b). Assume that every such weight is stored inside arc (v″, w″) of CDAWG″, and that weights are preserved when building CDAWG_T. Then, one plus the sum of all weights in the source-to-sink path of CDAWG_T that corresponds to suffix T[i..|T|] is the lexicographic rank of suffix T[i..|T|] (see e.g. Figures 1d and 1e). Equivalently:

► Property 4. Let arc (u, v) of CDAWG_T be weighted by sp(v) − sp(u), where v′ (respectively, u′) is a node of ST_T that belongs to the equivalence class of v (respectively, u), and v′ is a child of u′ in ST_T. Then, the lexicographic rank of suffix T[i..|T|] is one plus the sum of all weights in the path from the root of T(CDAWG_T) to the i-th leaf of T(CDAWG_T) in depth-first order.

2.4 Representing the suffix tree with the CDAWG

It is known that Properties 1 and 2 enable two encodings of ST_T that take O(ε_T + e_T) words of space each, and that support the operations in Table 2 with the specified time complexities [4]. Since the rest of this paper builds on the representation described in [4], we summarize it here for completeness.

It is known that |R_T| is at most the number of arcs in CDAWG_T [4], thus augmenting CDAWG_T with RLBWT_T does not increase space asymptotically. For every node v of
CDAWG\(_T\), we store: \(|\ell(v)|\) in a variable \(v.\text{length}\); the number \(v.\text{size}\) of right-maximal strings that belong to its equivalence class; the interval \([v.\text{first}..v.\text{last}]\) of \(\ell(v)\) in \(\text{BWT}\_T\); a linear-space predecessor data structure \([26]\) on the boundaries induced on the equivalence class of \(v\) by its in-neighbors (Property 2); and pointers to the in-neighbor that corresponds to the interval associated with each boundary. For every arc \(\gamma = (v, w)\) of CDAWG\(_T\), we store the first character of \(\ell(\gamma)\) in a variable \(\gamma.\text{char}\), and the number of characters of the right-extension implied by \(\gamma\) in a variable \(\gamma.\text{right}\). We also add to the CDAWG all arcs \((v, w, c)\) such that \(w\) is the equivalence class of the destination of a Weiner link from \(v\) labeled by character \(c\) in \(\text{BWT}\_T\), and the reverse of all explicit Weiner link arcs. We represent a node \(v\) of \(\text{ST}\_T\) as a tuple \(\text{id}(v) = (v', |\ell(v)|, i, j)\), where \(v'\) is the node in CDAWG\(_T\) that corresponds to the equivalence class of \(v\), and \([i..j]\) is the interval of \(\ell(v)\) in \(\text{BWT}\_T\). Implementing operations \(\text{stringDepth}(\text{id}(v))\), \(\text{nLeaves}(\text{id}(v))\) (which returns the number of leaves of the subtree of \(\text{ST}\_T\) rooted at a given node), \(\text{isAncestor}(\text{id}(v), \text{id}(w))\) (which returns true iff a node \(v\) of \(\text{ST}\_T\) is an ancestor of another node \(w\) of \(\text{ST}\_T\)), \(\text{suffixLink}(\text{id}(v))\), \(\text{weinerLink}(\text{id}(v))\), \(\text{locateLeaf}(\text{id}(v))\) (which returns the position of a leaf \(v\) of \(\text{ST}\_T\) in lexigraphic order) is straightforward using Properties 1.3 and 1.4, and implementing \(\text{parent}(\text{id}(v))\), \(\text{child}(\text{id}(v))\) and \(\text{nextSibling}(\text{id}(v))\) is easy using Properties 2 and 1.5.

Removing all implicit Weiner link arcs from our data structure achieves \(O(\text{c} \text{T})\) words of space, and still supports all queries except following implicit Weiner links. We can further drop \(\text{RLBWT}\_T\) and remove from \(\text{id}(v)\) the interval of \(\ell(v)\) in \(\text{BWT}\_T\), still supporting most of the original queries in the same amount of time, and \(\text{suffixLink}\) in constant time. The data structure after such removals corresponds to the second row of Table 2. Conversely, storing also the \(\text{RLBWT}\) of \(\overline{T}\), and the interval in such \(\text{RLBWT}\) of the reverse of the maximal repeat that corresponds to every node of the CDAWG, allows one to also read the label of an edge \(\gamma\) of \(\text{ST}\_T\) in \(O(\log \log \text{n})\) time per character, for the same asymptotic space complexity.

### 3 Additional suffix tree operations

In this paper we augment the representation of the suffix tree described in Section 2.4, enabling it to support a number of additional suffix tree operations in \(O(\log \text{n})\) time without increasing space complexity asymptotically. At the core of our methods lies a heavy path decomposition of CDAWG\(_T\) along the lines of [7], which we summarize in what follows to keep the paper self-contained.

**Definition 2** (Smooth function). Let \(T\) be a tree, let \(v_1, v_2, \ldots, v_N\) be its \(N\) leaves in depth-first order, let \(f\) be a function that assigns a real number to every leaf, and let \(F[1..N]\) be the array that stores at position \(i\) the value of \(f(v_i)\). We say that \(f\) is smooth with respect to \(T\) iff \(F[s\text{p}(v)..<s\text{p}(w)] = F[s\text{p}(v)..s\text{p}(w)]\) for every pair of internal nodes \(v, w\) of \(T\) that are generated by the same node of \(\mathcal{G}(T)\).

For example, let \(T\) be the parse tree of a string \(S\) generated by a context-free grammar; the function that assigns character \(T[i]\) to every position \(i\) of \(T\) is smooth.

**Lemma 3** ([7]). Let \(G\) be a DAG with \(n\) arcs such that every node has exactly two out-neighbors, let \(f\) be a smooth function with respect to \(\mathcal{T}(G)\), and let \(N\) be the number of leaves of \(\mathcal{T}(G)\). There is a data structure that, given a number \(i \in [1..N]\), returns \(f(u_i)\) in \(O(\log N)\) time, where \(u_i\) is the \(i\)-th leaf of \(\mathcal{T}(G)\) in depth-first order. Moreover, given two integers \(1 \leq i \leq j \leq N\), the data structure returns in \(O(\log N)\) time the node of \(G\) that corresponds to \(l\text{ca}(u_i, u_j)\), and it returns in \(O(\log N + j - i)\) time the sequence of values
Representing the Suffix Tree with the CDAWG

7:8 Representing the Suffix Tree with the CDAWG

\( f(u_1), f(u_{i+1}), \ldots, f(u_j) \), where \( u_k \) is the \( h \)-th leaf of \( T(G) \) in depth-first order. Such data structure takes \( O(n) \) words of space.

**Proof Sketch.** For each heavy path \( v_1, \ldots, v_k \) of \( T(G) \), we store at \( v_i \) values \( n\text{leaves}(v_i) \), \( \text{left}(v_i, v_j), f(v_i) \), a predecessor data structure on the set of values \( \{ \text{left}(v_i, v_j) : i \in [2..k] \} \), and a predecessor data structure on the set of values \( \{ \text{right}(v_i, v_j) : i \in [2..k] \} \). We expand every node \( v_i \) with position \( i_1 \) of a leaf in the subtree rooted at \( v_i \), such data structures allow us to detect the largest \( j \in [1..k] \) such that \( v_j \) is an ancestor of the query leaf. If \( j = k \) we return \( f(v_k) \), otherwise we take the light edge \((v_j, w)\) and we recur on \( w \), which is itself the first node of a heavy path. This solution takes \( O(\log N) \) queries to prefix-sum data structures, but the total size of all prefix-sum data structures can be \( O(N^2) \).

Note that a predecessor query on the left and right predecessor data structures stored at the first node \( v_1 \) of a heavy path of \( T(G) \) can be implemented with a weighted ancestor query\(^1\) on \( \tau(G) \), if we assign to each arc \((v, w)\) of \( G \) that also belongs to \( \tau(G) \) a left weight equal to zero if \( w \) is the left successor of \( v \), and equal to the number of leaves in the left successor of \( v \) otherwise (the right weight is defined similarly). Using a suitable data structure for weighted ancestor queries allows one to achieve \( O(n) \) words of space and overall \( O(\log N \cdot \log \log N) \) query time after \( O(n) \) preprocessing of \( G \). More advanced data structures that implement weighted ancestor queries on \( \tau(G) \) allow one to achieve the claimed bounds [7].

Given \( T(G) \), we proceed as follows to extract the values of all leaves in a depth-first interval \([i..j]\). Inside every node \( v \) of a heavy path, we store an auxiliary left pointer to the closest descendant of \( v \) in the heavy path whose right child is light. We symmetrically store an auxiliary left pointer. Then, we traverse \( T(G) \) top-down as described above, but searching for both the \( i \)-th leaf \( u_i \) and the \( j \)-th leaf \( u_j \) at the same time: when the nodes \( w \) and \( w' \) of \( G \) that result from such searches are different, we know that one is a descendant of the other in \( \tau(G) \), and the node of \( G \) that corresponds to \( \text{lca}(u_i, u_j) \) in \( T(G) \) is the one whose number of leaves equals \( \max\{n\text{leaves}(w), n\text{leaves}(w')\} \). Then we continue the search for the two leaves separately: during the search for \( u_i \) (respectively, \( u_j \)) we follow all right (respectively, left) auxiliary pointers in all heavy paths, and we concatenate the corresponding nodes in a left (respectively, right) linked list. The size of such lists is \( O(j - i) \), and computing sequence \( f(u_i), \ldots, f(u_j) \) from the lists takes \( O(j - i) \) time. The same approach can be applied to \( G \), at the cost of \( O(n) \) preprocessing time and space.

Since a node \( v \) of \( T(G) \) can be uniquely identified by an interval of leaves in depth-first order, Lemma 3 effectively implements a map from the identifier of a node in \( T(G) \) to the identifier of its corresponding node in \( G \).

**Lemma 4.** Lemma 3 holds also for a DAG in which all nodes have out-degree at least two.

**Proof.** We expand every node \( v \) with out-degree \( d > 2 \) into a binary directed tree, with \( d - 1 \) artificial internal nodes, whose \( d \) leaves are the out-neighbors of \( v \) in \( G \). We also store in each artificial internal node \( w \) a pointer \( w.\text{real} = v \). The size of such expanded DAG \( G' \) is still \( O(n) \), where \( n \) is the number of arcs of \( G \). \( T(G') \) is a binary tree with the same number of leaves as \( T(G) \), there is a bijection between the leaves of \( T(G) \) and the leaves of \( T(G') \) such that the \( i \)-th leaf in depth-first order in \( T(G) \) corresponds to the \( i \)-th leaf in depth-first order in \( T(G') \), and the extension of \( f \) to the leaves of \( T(G') \) induced by such bijection is

---

\(^1\) A weighted ancestor query \((v, k)\) on a tree with weights on the edges asks for the lowest ancestor \( u \) of a node \( v \) such that the sum of weights in the path from \( u \) to \( v \) is at least \( k \) [2].
smooth with respect to $T(G')$. Note that, if Lemma 3 returns an artificial node $w$ as the result of a lowest common ancestor query, it suffices to return $w.\text{real}$ instead.

Lemma 3 can be adapted to support queries on another class of functions:

- **Definition 5 (Telescoping function).** Let $f$ be a function that assigns a real number to any path of any weighted graph. We say that $f$ is telescoping iff:
  1. Given a path $P = v_1, v_2, \ldots, v_k$, $f(P) = g(\omega(v_1, v_2)) \circ \cdots \circ g(\omega(v_{k-1}, v_k))$, where $\omega(v_i, v_j)$ is the weight of edge or arc $(v_i, v_j)$, $g$ is a function that can be computed in constant time, and $x \circ y$ is a binary associative operator with identity element $I$ that can be computed in constant time.
  2. $f(v_1, \ldots, v_k) \geq f(v_i, \ldots, v_i)$ for all $i < k$, and $f(v_1, \ldots, v_k) \geq f(v_i, \ldots, v_i)$ for all $i > 1$.
  3. For every path $v_1, v_i, \ldots, v_j, v_k$, $f(v_i, \ldots, v_j)$ can be computed in constant time given $f(v_1, \ldots, v_i)$ and $f(v_1, \ldots, v_k)$, or given $f(v_i, \ldots, v_k)$ and $f(v_j, \ldots, v_k)$.

We call $y$ the inverse of $x$ with respect to $\circ$ iff $x \circ y = y \circ x = I$. For example, the sum of edge weights in a path is telescoping, $I = 0$, and the inverse of $x$ is $-x$. Note that a telescoping function is not necessarily smooth.

- **Lemma 6.** Let $G$ be a weighted DAG with $n$ arcs in which every node has at least two out-neighbors, let $f$ be a telescoping function, and let $N$ be the number of leaves of $T(G)$. There is a data structure that, given a number $i \in [1..N]$, evaluates $f$ in $O(\log N)$ time on the path from the root of $T(G)$ to the $i$-th leaf in depth-first order. Moreover, given two numbers $1 \leq i < j \leq N$, the data structure:
  1. Evaluates $f$ in $O(\log N)$ time on the path from the root of $T(G)$ to $\text{lca}(u_i, u_j)$, where $u_i$ and $u_j$ are the $i$-th and $j$-th leaf of $T(G)$ in depth-first order.
  2. Returns in $O(\log N + j - i)$ time the sequence of values $f(u_i), f(u_{i+1}), \ldots, f(u_j)$, where $f(u_k)$ is the value of function $f$ evaluated on the path from the root of $T(G)$ to the $k$-th leaf in depth-first order.
  3. If $[i..j]$ is the identifier of node $v$ in $T(G)$, given a nonnegative number $k$, returns in $O(\log N)$ time the node of $G$ that corresponds to the highest ancestor $w$ of $v$ in $T(G)$ such that $f$, evaluated on the path from the root of $T(G)$ to $w$, is at least $k$ (weighted ancestor query).

Such data structure takes $O(n)$ words of space.

**Proof.** If a node $v$ in the DAG has out-degree greater than two, we expand it as described in Lemma 4, assigning weight $\|v\|$ to all arcs that end in an artificial internal node of the expanded DAG, and assigning the weight of arc $(v, w)$ to the arc that connects an artificial internal node to out-neighbor $w$ of $v$ in $G$. We also store a pointer to $v$ inside each artificial internal node. Let $G'$ be the expanded version of $G$. At every node $v$ of $G'$ we store variable $v.\text{count} = f(P(v))$, where $P(v)$ is the path from $v$ to the sink of $G'$ that uses only arcs in the spanning tree $\tau(G')$. We traverse $G'$ as described in Lemma 3: at the current node $v$, we compute its highest ancestor $v$ in $\tau(G')$ that lies in the path, from the source of $G'$ to the sink of $G'$, that corresponds to the $i$-th leaf of $T(G')$. We use $u.\text{count}$ and $v.\text{count}$ to evaluate $f$ in constant time on the path from $u$ to $v$ along $\tau(G')$, and we cumulate such value to the output. For each arc $(v, w)$ that does not belong to $\tau(G')$, we compute $g(\omega(v, w))$ and we cumulate it to the output.

To evaluate $f$ on the path from the root of $T(G)$ to $\text{lca}(v_i, v_j)$, we follow the extraction strategy described in Lemma 3, using in the last step $u.\text{count}$ and $v.\text{count}$, where $u$ is the current node and $v$ is the (possibly artificial) node of $G'$ that corresponds to $\text{lca}(v_i, v_j)$ in $T(G')$. We use the extraction strategy of Lemma 3 also to evaluate $f$ on all leaves of $T(G)$.
in the depth-first interval \([i..j]\): every time we take a right pointer or a left pointer \((u, v)\), we cumulate weight \(u\.\text{count} \circ y\) to the current value of \(f\), where \(y\) is the inverse of \(v\.\text{count}\), and we start from such value of \(f\) when visiting the subgraph of \(G'\) that starts at \(v\).

To support weighted ancestor queries on \(f\) and \(\mathcal{T}(G)\), we build a data structure that supports level ancestor queries on \(\tau(G')\): given a node \(v\) and a path length \(d\), such data structure returns the ancestor \(u\) of \(v\) in \(\tau(G')\) such that the path from the root of \(\tau(G')\) to \(u\) contains exactly \(d\) nodes. The level ancestor data structure described in \([5, 6]\) takes \(O(n)\) words of space and it answers queries in constant time. We search again for the \(i\)-th and \(j\)-th leaf in parallel, cumulating \(\tau\) using the weights of light arcs and of heavy paths as done before. Let \(u\) be the current node in this search, and let \(x\) be the current value of \(f\): if \(x < k\), but the value of \(f\) is at least \(k\) at the next node \(v\) such that the path from \(u\) to \(v\) in \(G'\) belongs to \(\tau(G')\), we binary search the nodes \(w\) on the path from \(u\) to \(v\), using level ancestor queries from \(u\) and comparing \(x \circ u\.\text{count} \circ y\) to \(k\), where \(y\) is the inverse of \(u\.\text{count}\). The result of the binary search is not an artificial node.

Let \([i..j]\) be the identifier of a node of \(\mathcal{T}(G)\), and let \([i'..j']\) be the identifier of its weighted ancestor. Since it is easy to transform the node of \(G\) that corresponds to \([i'..j']\) into interval \([i'..j']\) itself, Lemma 6 effectively implements a map from \([i..j]\) to \([i'..j']\) in \(O(\log N)\) time.

Applying Lemma 6 to \(\text{CDAWG}_T\) is all we need to support the additional operations in Table 1 efficiently:

\textbf{Theorem 7.} Let \(T \in [1..n]^{n-1}\) # be a string. There are two representations of \(\text{ST}_T\) that support the operations in Table 1 and in Table 2 with the specified time and space complexities.

\textbf{Proof.} Operation \texttt{selectLeaf}(\(i\)) returns an identifier of the \(i\)-th leaf of \(\text{ST}_T\) in lexicographic order. Recall from Section 2.4 that we store in a variable \(\gamma\.\text{right}\) the number of characters of the right extension implied by arc \(\gamma\) of \(\text{CDAWG}_T\). Thus, the length of the suffix associated with a leaf of \(\text{ST}_T\) (or equivalently, the position of that leaf in right-to-left string order) is the sum of all weights in the source-to-sink path of \(\text{CDAWG}_T\) that corresponds to the leaf. Since the sum of such weights is a telescoping function, we use the data structures in Lemma 6, built on these weights, to compute the value of \(|s|\) in \(O(\log n)\) time, and we return \(|s| - 1\) instead is enough to implement \(\text{SA}_T[i]\). Since Lemma 6 supports also the extraction of all values of a telescoping function inside a depth-first range of leaves \([i..j]\), implementing \(\text{SA}_T[i..j]\) is straightforward.

Operation \texttt{lca}(\(i, j\)) returns the identifier of the lowest common ancestor, in \(\text{ST}_T\), of the \(i\)-th and the \(j\)-th leaf in lexicographic order. We use Lemma 6 to compute both the node \(v\) of \(\text{CDAWG}_T\) that corresponds to such common ancestor, and its string depth \(s\), returning tuple \((v, s, x, y)\), where the range \([x..y] \supseteq [i..j]\) of the lowest common ancestor is computed during the top-down traversal of \(\text{CDAWG}_T\) using the weighted ancestor data structure on \(\tau(\text{CDAWG}_T)\). A similar approach allows one to return \(\text{LCP}[i]\), and a slight variation of the approach used to compute \(\text{SA}_T[i..j]\) supports also \(\text{LCP}[i..j]\). Operation \texttt{depth}(\(\text{id}(v)\)) returns the depth of the node \(v\) of \(\text{ST}_T\) whose identifier is \(\text{id}(v)\). Since \(\text{id}(v)\) contains the range \([i..j]\) of \(v\) in \(\text{BWT}_T\), we can proceed as in operation \texttt{lca}(\(i, j\)), and return the length of the path that the search traversed from the source of \(\text{CDAWG}_T\) to the node of \(\text{CDAWG}_T\) that corresponds to \(v\). Operation \texttt{leftmostLeaf}(\(\text{id}(v)\)) returns the identifier of the smallest leaf in lexicographic order in the subtree of \(\text{ST}_T\) rooted at node \(v\). Let \(\text{id}(v) = (v', \ell, i, j)\), and let \(W\) be the longest maximal repeat in the equivalence class of node \(v'\). Then, \texttt{leftmostLeaf}(\(\text{id}(v)\)) = \((w'\leftarrow \ell + v'.\text{left}, i, i)\), where \(w'\) is the sink of \(\text{CDAWG}_T\), and \(v'.\text{left}\) is the string length of the path, in \(\text{ST}_T\), that goes from the node of \(\text{ST}_T\) with string label \(W\) to its leftmost leaf. We store \(v'.\text{left}\) at every node
of the CDAWG. Operation \texttt{rightmostLeaf} can be handled symmetrically. Operation \texttt{stringAncestor(id(v), d)} (respectively, \texttt{ancestor(id(v), d)}) returns the identifier of the highest ancestor of v in ST\textsubscript{T} whose string depth (respectively, depth) is at least d. This can be implemented with the weighted ancestor query provided by Lemma 6, where the weight of arc $\gamma$ of CDAWG\textsubscript{T} is $\gamma, \text{right}$ (respectively, one).

Finally, by Property 4, we support access to the value of the inverse suffix array at string position i by building the data structures of Lemma 6 on the compacted CDAWG\textsubscript{T}, with arc weights corresponding to offsets between nested BWT intervals, and with a weighted ancestor data structure on $\tau(CDAWG\textsubscript{T})$ based on offsets between string positions. Note that all arcs that end at the same node of the compacted CDAWG\textsubscript{T} have distinct weights. Then, we evaluate the sum of edge weights from the root of $T(CDAWG\textsubscript{T})$ to its i-th leaf in depth-first order. Implementing $ISA_T[[i..j]]$ is also straightforward, and PLCP[i] can be supported using $ISA_T[i]$. Assume that, while building CDAWG\textsubscript{T}, we keep the first character of the label of every arc of CDAWG\textsubscript{T} that starts from the root, we propagate it during compaction, and we store it at the nodes as described in Lemma 3. Then, since $T(CDAWG\textsubscript{T})$ is a parse tree of $T$, we can also return $T[i]$ in $O(\log n)$ time and $T[i..j]$ in $O(\log n + j - i)$ time. Since the compacted reversed CDAWG is a grammar for $T$, the time for extracting $T[i..j]$ can be reduced to $O(\log n + (j - i)/\log n)$ by using the access query described in [3].

\begin{corollary}
Given a string $T \in [1..\sigma]^{n-1}$#, there is a representation of the suffix array of $T$, of the inverse suffix array of $T$, of the LCP array of $T$, of the permuted LCP array of $T$, and of $T$ itself, that takes $O(e_T)$ words of space, and that supports random access to any position in $O(\log n)$ time.
\end{corollary}

Note that Corollary 8 yields immediately a representation of the compressed suffix array of $T$ [22] that takes $O(e_T)$ words of space.

\section{Extensions and conclusion}

Our data structures provide immediate support for a number of queries of common use in pattern matching, in addition to those listed in Tables 1 and 2. For example, recall that an internal pattern matching query $(i, j)$ asks for all the $occ$ starting positions of $T[i..j]$ inside a string $T$ of length $n$. We can support such query in $O(\log n + occ)$ time, by combining an inverse suffix array query, a string ancestor query, and the extraction strategy of Lemma 6. Similarly, combining an inverse suffix array query with a lowest common ancestor query and a string depth query, allows one to compute the longest common prefix between two given suffixes of $T$ in $O(\log n)$ time. Along the same lines, operation $\texttt{letter(id(v), i)}$, which returns the i-th character of the label of node v of the suffix tree, can be supported in $O(\log n)$ time. We can also implement in constant time operation $\texttt{deepestNode(id(v))}$, which returns the identifier of the first node with largest depth (or string depth) in the subtree of the suffix tree rooted at $v$ [19]. If we choose not to store the BWT intervals of the nodes of the CDAWG as in the second row of Tables 1 and 2, we can implement in $O(\log n)$ time operation $\texttt{suffixLink(id(v), i)}$, which returns the identifier of the node of the suffix tree that is reachable from v after taking i suffix links. This can be done by computing $1ca(id(u), id(v))$, where $id(v) = (v', k, a, b)$, $id(u) = (z, e, x, c)$, $id(w) = (z, f, y, y)$, $z$ is the sink of the CDAWG, $e = |T| - \text{SA}[a] + i + 1$, $f = |T| - \text{SA}[b] + i + 1$, $x = \text{ISA}[\text{SA}[a] + i]$ and $y = \text{ISA}[\text{SA}[b] + i]$. By using the representation described in [7], we can also support in $O(\log n)$ time operations like $\text{preorderSelect}(i)$, $\text{postorderSelect}(i)$, $\text{preorderRank}(v)$, $\text{postorderRank}(v)$, $\text{treeLevelSuccessor}(v)$ and
Representing the Suffix Tree with the CDAWG

However, some operations on the topology of the suffix tree are not yet implemented by our data structures (see e.g. [19]): it would be interesting to know whether they can be supported efficiently within the same space budget.

Recall from Section 2.4 that our current representation of the suffix tree supports reading the label of an arc in $O(\log \log n)$ time per character, using the RLBWT of $T$. It would be interesting to know whether this bound can be improved, and whether the RLBWT of $T$ can be dropped. Another question for further research is whether the ubiquitous $O(\log n)$ term in Table 1 can be reduced while keeping the same asymptotic space budget, or whether a lower bound makes it impossible, along the lines of [25].

On the applied side, it is not yet clear whether there is a subset of our algorithms that is practically applicable, and whether it could achieve competitive tradeoffs with respect to state-of-the-art suffix tree representations for highly repetitive collections. It would also be interesting to try and use our data structures for tuning specific applications to repetitive strings in practice, like matching statistics and substring kernels. For example, it turns out that some weighting functions used in substring kernels are telescoping [24]. Since our data structures support matching statistics [4], and since the computation of some substring kernels can be mapped onto matching statistics [24], we can compute some substring kernels between a fixed $T$ and a query string of length $m$ in $O(m \log n)$ time, using a data structure that takes just $O(e_T)$ words of space.

Abstract

We propose a new indexing structure for parameterized strings, called parameterized position heap. Parameterized position heap is applicable for parameterized pattern matching problem, where the pattern matches a substring of the text if there exists a bijective mapping from the symbols of the pattern to the symbols of the substring. We propose an online construction algorithm of parameterized position heap of a text and show that our algorithm runs in linear time with respect to the text size. We also show that by using parameterized position heap, we can find all occurrences of a pattern in the text in linear time with respect to the product of the pattern size and the alphabet size.

1 Introduction

String matching problem is to find occurrences of a pattern string in a text string. Formally, given a text string $t$ and a pattern string $p$ over an alphabet $\Sigma$, output all positions at which $p$ occurs in $t$. Suffix tree and suffix array are most widely used data structures and provide many applications for various string matchings (see e.g. [11, 6]).

Ehrenfeucht et al. [8] proposed an indexing structure for string matching, called a position heap. Position heap uses less memory than suffix tree does, and provides efficient search of patterns by preprocessing the text string, similarly to suffix tree and suffix array. A position heap for a string $t$ is a sequence hash tree [4] for the ordered set of all suffixes of $t$. In [8], the suffixes are ordered in the ascending order of length, and the proposed construction algorithm processes the text from right to left. Later, Kucherov [13] considered the ordered set of suffixes in the descending order of length and proposed a linear-time
online construction algorithm based on the Ukkonen’s algorithm \[16\]. Nakashima et al. \[14\] proposed an algorithm to construct a position heap for a set of strings, where the input is given as a trie of the set. Gagie et al. \[10\] proposed a position heap with limited height and showed some relations between position heap and suffix array.

The parameterized pattern matching that focuses on a structure of strings is introduced by Baker \[2\]. Let \(\Sigma\) and \(\Pi\) be two disjoint sets of symbols. A string over \(\Sigma \cup \Pi\) is called a parameterized string (p-string for short). In the parameterized pattern matching problem, given p-strings \(t\) and \(p\), find positions of substrings of \(t\) that can be transformed into \(p\) by applying one-to-one function that renames symbols in \(\Pi\). The parameterized pattern matching is motivated by applying to the software maintenance \[1, 2, 3\], the plagiarism detection \[9\], the analysis of gene structure \[15\], and so on. Similar to the basic string matching problem, some indexing structures that support the parameterized pattern matching are proposed, such as parameterized suffix tree \[2\], structural suffix tree \[15\], and parameterized suffix array \[7, 12\].

In this paper, we propose a new indexing structure called parameterized position heap for the parameterized pattern matching. The parameterized position heap is a sequence hash tree array \[7, 12\].

Some indexing structures that support the parameterized pattern matching are proposed, such as parameterized suffix tree \[2\], structural suffix tree \[15\], and parameterized suffix array \[7, 12\].

### 2 Notation

Let \(\Sigma\) and \(\Pi\) be two disjoint sets of symbols. \(\Sigma\) is a set of constant symbols and \(\Pi\) is a set of parameter symbols. An element of \(\Sigma^*\) is called a string, and an element of \((\Sigma \cup \Pi)^*\) is called a parameterized string, or p-string for short. For a p-string \(w = xyz, x, y,\) and \(z\) are called prefix, substring, and suffix of \(w\), respectively. \(|w|\) denotes the length of \(w\), and \(w[i]\) denotes the \(i\)-th symbol of \(w\) for \(1 \leq i \leq |w|\). The substring of \(w\) that begins at position \(i\) and ends at position \(j\) is denoted by \(w[i : j]\) for \(1 \leq i \leq j \leq |w|\). Moreover, let \(w[i : j] = w[1:i] \text{ and } w[i : j] = w[i : |w|]\) for \(1 \leq i \leq |w|\). The empty p-string is denoted by \(\emptyset\), that is \(|\emptyset| = 0\). For convenience, let \(w[i : j] = \emptyset\) if \(i > j\). Let \(\mathcal{N}\) denote the set of all non-negative integers.

Given two p-strings \(w_1\) and \(w_2\), \(w_1\) and \(w_2\) are a parameterized match or p-match, denoted by \(w_1 \approx w_2\), if there exists a bijection \(f\) from the symbols of \(w_1\) to the symbols of \(w_2\), such that \(f\) is identity on the constant symbols \[2\]. We can determine whether \(w_1 \approx w_2\) or not by using an encoding called prev-encoding defined as follows.

**Definition 1** (Prev-encoding \[2\]). For a p-string \(w\) over \(\Sigma \cup \Pi\), the prev-encoding for \(w\), denoted by \(\text{prev}(w)\), is a string \(x\) of length \(|w|\) over \(\Sigma \cup \mathcal{N}\) defined by

\[
x[i] = \begin{cases} 
  w[i] & \text{if } w[i] \in \Sigma, \\
  0 & \text{if } w[i] \in \Pi \text{ and } w[i] \neq w[j] \text{ for } 1 \leq j < i, \\
  i - \max\{j \mid w[j] = w[i] \text{ and } 1 \leq j < i\} & \text{otherwise}.
\end{cases}
\]

For any p-strings \(w_1\) and \(w_2\), \(w_1 \approx w_2\) if and only if \(\text{prev}(w_1) = \text{prev}(w_2)\). For example, given \(\Sigma = \{a, b\}\) and \(\Pi = \{u, v, x, y\}\), \(s_1 = uvvuvuab\) and \(s_2 = xyxyaxxyb\) are p-matches where \(\text{prev}(s_1) = \text{prev}(s_2) = 0022a314b\).

The parameterized pattern matching is a problem to find occurrences of a p-string pattern in a p-string text defined as follows.
(b) A position heap for a string \texttt{abababaabaabab}. (c) An augmented position heap for a string \texttt{abababaabaabab}. Maximal-reach pointers for \texttt{mrp}(i) \neq i are illustrated by doublet arrows.

Definition 2 (Parameterized pattern matching [2]). Given two \( p \)-strings, text \( t \) and pattern \( p \), find all positions \( i \) in \( t \) such that \( t[i : i + |p| - 1] \approx p \).

For example, let us consider a text \( t = uraubaarbe \) and a pattern \( p = xayby \) over \( \Sigma = \{a, b\} \) and \( \Pi = \{u, v, x, y\} \). Because \( p \approx t[2 : 6] \) and \( p \approx t[6 : 10] \), we should output 2 and 6.

Throughout this paper, let \( t \) be a text of length \( n \) and \( p \) be a pattern of length \( m \).

3 Position Heap

In this section, we briefly review the position heap for strings. First we introduce the sequence hash tree that is a trie for hashing proposed by Coffman and Eve [4]. Each edge of the trie is labeled by a symbol and each node can be identified with the string obtained by concatenating all labels found on the path from root to the node.

Definition 3 (Sequence Hash Tree). Let \( W = (w_1, \ldots, w_n) \) be an ordered set of strings over \( \Sigma \) and \( W_i = (w_1, \ldots, w_i) \) for \( 1 \leq i \leq n \). A sequence hash tree \( SHT(W) = (V_n, E_n) \) for \( W \) is a trie over \( \Sigma \) defined recursively as follows. Let \( SHT(W_i) = (V_i, E_i) \). Then,

\[
SHT(W_i) = \begin{cases} 
\{(\varepsilon, \emptyset)\} & (\text{if } i = 0), \\
(V_{i-1} \cup \{p_i\}, E_{i-1} \cup \{(q_i, c, p_i)\}) & (\text{if } 1 \leq i \leq n).
\end{cases}
\]

where \( p_i \) is the shortest prefix of \( w_i \) such that \( p_i \notin V_{i-1} \), and \( q_i = w_{i[1 : |p_i| - 1]}, c = w_{i[|p_i|]} \). If no such \( p_i \) exists, then \( V_i = V_{i-1} \) and \( E_i = E_{i-1} \).

Each node in a sequence hash tree stores one or several indices of strings in the input set. An example of a sequence hash tree is shown in Figure 1 (a).

The position heap proposed by Ehrenfeucht et al. [8] is a sequence hash tree for the ordered set of all suffixes of a string. Two types of position heap are known. The first one is proposed by Ehrenfeucht et al. [8], that constructed by the ordered set of suffixes in ascending order of length and the second one is proposed by Kucherov [13], which constructed in descending order. We adopt the Kucherov [13] type and his online construction algorithm for constructing position heaps for parameterized strings in Section 4. Here we recall the definition of the position heap by Kucherov.

Definition 4 (Position Heap [13]). Given a string \( t \in \Sigma^n \), let \( S_t = (t[1:], t[2:], \ldots, t[n:]) \) be the ordered set of all suffixes of \( t \) except \( \varepsilon \) in descending order of length. The position heap \( PH(t) \) for \( t \) is \( SHT(S_t) \).
Each node except the root in a position heap stores either one or two integers those are beginning positions of corresponding suffixes. We call them regular node and double node respectively. Assume that \( i \) and \( j \) are positions stored by a double node \( v \) in \( PH(t) \) where \( i < j \), \( i \) and \( j \) are called the primary position and the secondary position respectively. Figure 1 (b) shows an example of a position heap.

In order to find occurrences of the pattern in \( O(m + \text{occ}) \) time, Ehrenfeucht et al. [8] and Kucherov [13] added additional pointer called maximal-reach pointer to the position heap and called this extended data structure as augmented position heap. An example of an augmented position heap is showed in Figure 1 (c).

### 4 Parameterized Position Heap

In this section, we propose a new indexing structure called parameterized position heap. It is based on the position heap proposed by Kucherov [13].

#### 4.1 Definition and Property of Parameterized Position Heap

The parameterized position heap is a sequence hash tree [4] for the ordered set of prev-encoded suffixes in the descending order of length.

**Definition 5 (Parameterized Position Heap).** Given a p-string \( t \in (\Sigma \cup \Pi)^n \), let \( S_t = (\text{prev}(t[1 :) ), \text{prev}(t[2 :) ), \ldots, \text{prev}(t[n :) )) \) be the ordered set of all prev-encoded suffixes of the p-string \( t \) except \( \varepsilon \) in descending order of length. The parameterized position heap \( PPH(t) \) for \( t \) is \( SHT(S_t) \).

Figure 2 (a) shows an example of a parameterized position heap. A parameterized position heap \( PPH(t) \) for a p-string \( t \) of length \( n \) consists of the root and nodes that corresponds to \( \text{prev}(t[1 :) ), \text{prev}(t[2 :) ), \ldots, \text{prev}(t[n :) )) \), so \( PPH(t) \) has at most \( n + 1 \) nodes. Each node in \( PPH(t) \) holds either one or two of beginning positions of corresponding p-suffixes similar to the standard position heaps. We can specify each node in \( PPH(t) \) by its primary position, its secondary position, or the string obtained by concatenating labels found on the path from the root to the node.

Different from standard position heap, \( \text{prev}(t[i :) ) = \text{prev}(t)[i :) \) does not necessarily hold for some cases. For example, for \( t = xaxyxyxyx \), \( \text{prev}(t[3 :) ) = 0022221a4322 \) while \( \text{prev}(t)[3 :) = 0222221a4322 \). Therefore, the construction and matching algorithms for the
standard position heaps cannot be directly applied for the parameterized position heaps. However, we can similar properties to construct parameterized position heaps efficiently.

Lemma 6. For i and j, where 1 ≤ i ≤ j ≤ n, if prev(t[i : j]) is represented in PH(t), then a prev-encoded string for any substring of t[i : j] is also represented in PH(t).

Proof. First we will show that prev-encoding of any prefix of t[i : j] is represented in PH(t). From the definition of prev-encoding, prev(t[i : j])[1 : i − j] = prev(t[i : j − 1]). In other words, prev(t[i : j − 1]) is a prefix of prev(t[i : j]). From the definition of PH(t), prefixes of prev(t[i : j]) are represented in PH(t). Therefore, prev(t[i : j − 1]) is represented in PH(t). Similarly, prev(t[i : j − 2]), · · · , prev(t[i : i]) are represented in PH(t).

Next, we will show that prev-encoding of any suffix of t[i : j] is represented in PH(t). From the above discussion, there are positions b0 < b1 < · · · < bj−i = i in t such that prev(t[bk : bk + k]) = prev(t[i : i + k]). From the definition of parameterized position heap, prev(t[bk + 1 : bk + 1 + k + 1]) is represented in PH(t). Since prev(t[bk + 1 : bk + 1 + k]) is a prefix of prev(t[bk+1 : bk+1 + k + 1]) for 0 < k < j − i, if prev(t[bk + 1 : bk + k]) is represented in PH(t) then prev(t[bk+1 : bk+1 + k + 1]) is also represented in PH(t) recursively. Therefore, prev(t[bj−i + 1 : bj−i + j − i]) = prev(t[i + 1 : j]) is represented in PH(t). Similarly, prev(t[i + 2 : j]), · · · , prev(t[j : j]) are represented in PH(t).

Since any prefix and suffix of prev(t[i : j]) is represented in PH(t), we can say that any substring of prev(t[i : j]) is represented in PH(t) by induction.

4.2 Online Construction Algorithm of Parameterized Position Heap

In this section, we propose an online algorithm that constructs parameterized position heaps. Our algorithm is based on Kucherov’s algorithm, although it cannot be applied easily. The algorithm updates PH(t[1 : k]) to PH(t[1 : k + 1]) when t[k + 1] is read, where 1 ≤ k ≤ n − 1. Updating of the position heap begins from a special node, called the active node. A position specified by the active node is called the active position. At first, we show that there exists a position similar to the active position in the parameterized position heap.

Lemma 7. If j is a secondary position of a double node in a parameterized position heap, then j + 1 is also a secondary position.

Proof. Let i be the primary position and j be the secondary position of node v, where i < j. This means there is a position h such that prev(t[i : h]) = prev(t[j : ]). By Lemma 6, there is a node that represents prev(t[i + 1 : h]). Since prev(t[j + 1 : ]) = prev(t[i + 1 : h]), then j + 1 will be the secondary positions of node v(prev(t[i + 1 : h])).

Lemma 7 means that there exists a position s which splits all positions in t[1 : n] into two intervals, similar to the active position in [13]. Positions in [1 : s − 1] and [s : n] are called primary and secondary positions, respectively. We also call the position s as active position.

Assume we have constructed PH(t[1 : k]) and we want to construct PH(t[1 : k + 1]) from PH(t[1 : k]). The primary positions 1, . . . , s − 1 in PH(t[1 : k]) become primary positions also in PH(t[1 : k + 1]), because prev(t[i : k]) = prev(t[i : k + 1])[1 : k − 1 + 1] holds for 1 ≤ i ≤ s − 1. Therefore, we do not need to update the primary positions.

On the other hand, the secondary positions s, . . . , k require some modifications. When inserting a new symbol, two cases can occur. The first case is that prev(t[i : k + 1]) is not represented in PH(t[1 : k]). In this case, a new node prev(t[i : k + 1]) is created as a child node of prev(t[i : k]) and position i becomes the primary position of the new node. The second case is that prev(t[i : k + 1]) was already represented in PH(t[1 : k]). In this case,
For each node can be obtained by modifying \( \text{PPH}(xaxyxyxz) \) to \( \text{PPH}(xaxyxyxyz) \). The updated positions are colored red. The secondary positions 6 and 7 in \( \text{PPH}(xaxyxyxz) \) are become primary positions in \( \text{PPH}(xaxyxyxyz) \), while the secondary position 8 in \( \text{PPH}(xaxyxyxyz) \) is become a secondary position of another node in \( \text{PPH}(xaxyxyxyz) \). The active position is updated from 6 to 8.

the secondary position \( i \) that is stored in \( \text{prev}(t[i : k]) \) currently should be moved to the child node \( \text{prev}(t[i : k + 1]) \), and position \( i \) becomes the secondary position of this node.

From Lemma 6, if the node \( \text{prev}(t[i : k]) \) has an edge to the node \( \text{prev}(t[i : k + 1]) \), \( \text{prev}(t[i + 1 : k]) \) also has an edge to \( \text{prev}(t[i + 1 : k + 1]) \). Therefore, there exists \( r \), with \( 1 \leq s \leq r \leq k \), that splits the interval \( [s : k] \) into two subintervals \( [s : r - 1] \) and \( [r : k] \), such that the node \( \text{prev}(t[i : k]) \) does not have an edge to \( \text{prev}(t[i : k + 1]) \) for \( s \leq i \leq r - 1 \), and does have such an edge for \( r \leq i \leq k \).

The above analysis leads to the following lemma that specifies the modifications from \( \text{PPH}(t[1 : k]) \) to \( \text{PPH}(t[1 : k + 1]) \).

**Lemma 8.** Given \( t \in (\Sigma \cup \Pi)^n \), consider \( \text{PPH}(t[1 : k]) \) for \( k < n \). Let \( s \) be the active position, stored in the node \( \text{prev}(t[s : k]) \). Let \( r \geq s \) be the smallest position such that node \( \text{prev}(t[r : k]) \) has an outgoing edge labeled with \( \text{prev}(t[r : k + 1]) \) \( [k - r + 2] \). \( \text{PPH}(t[1 : k + 1]) \) can be obtained by modifying \( \text{PPH}(t[1 : k]) \) in the following way:

1. For each node \( \text{prev}(t[i : k]) \), \( s \leq i < r \), create a new child \( \text{prev}(t[i : k + 1]) \) linked by an edge labeled \( \text{prev}(t[i + 1 : k + 1]) \) \( [k - i + 2] \). Delete the secondary position \( i \) from the node \( \text{prev}(t[i : k]) \) and assign it as the primary position of the new node \( \text{prev}(t[i : k + 1]) \).
2. For each node \( \text{prev}(t[i : k]) \), \( r \leq i \leq k \), move the secondary position \( i \) from the node \( \text{prev}(t[i : k]) \) to the node \( \text{prev}(t[i : k + 1]) \).

Moreover, \( r \) will be the active position in \( \text{PPH}(t[1 : k + 1]) \).

**Proof.** Consider the first case that \( i \) be a secondary position in \( \text{PPH}(t[1 : k]) \) and \( s \leq i < r \). From the definition of \( r \), there is no node \( \text{prev}(t[i : k + 1]) \) in \( \text{PPH}(t[i : k]) \). Therefore, \( i \) will be a primary position of the node \( \text{prev}(t[i : k + 1]) \) in \( \text{PPH}(t[1 : k + 1]) \). We can update the position heap from \( \text{PPH}(t[1 : k]) \) to \( \text{PPH}(t[1 : k + 1]) \) by delete \( i \) from secondary position of the node \( \text{prev}(t[i : k]) \) and create a new node \( \text{prev}(t[i : k + 1]) \) and assign \( i \) to its primary position for the case \( s \leq i < r \).

Next case, \( i \) be a secondary position in \( \text{PPH}(t[1 : k]) \) and \( r \leq i \leq k \). In this case, there is a node \( \text{prev}(t[i : k + 1]) \) in \( \text{PPH}(t[i : k]) \) and the node \( \text{prev}(t[i : k + 1]) \) is also represented in \( \text{PPH}(t[i : k + 1]) \). Therefore, \( i \) will be a secondary position of the node \( \text{prev}(t[i : k + 1]) \) in
$PPH(t[1 : k + 1])$. We can update the position heap from $PPH(t[1 : k])$ to $PPH(t[1 : k + 1])$
by delete $i$ from secondary position of the node $prev(t[i : k])$ and assign $i$ as secondary
position of the node $prev(t[i : k + 1])$ for the case $r < i \leq k$.

Since position $i$ for $1 \leq i < r$ be a primary position in $PPH(t[1 : k + 1])$ and position $i$
for $r \leq i \leq k + 1$ be a secondary position in $PPH(t[1 : k + 1])$, $r$ will be the active position
in $PPH(t[1 : k + 1])$. ▶

Figure 3 show an example of updating a parameterized position heap. The modifications
specified by Lemma 8 need to be applied to all secondary positions. In order to perform
these modifications efficiently, we use parameterized suffix pointers.

$\triangleright$ **Definition 9 (Parameterized Suffix Pointer).** For each node $prev(t[i : j])$ of $PPH(t)$, the
parameterized suffix pointer of $prev(t[i : j])$ is defined by $psp(prev(t[i : j])) = prev(t[i + 1 : j])$.

By Lemma 6, whenever the node $prev(t[i : j])$ exists, the node $prev(t[i + 1 : j])$ exists too.
This means that $psp(prev(t[i : j]))$ always exists. During the construction of the parameterized
position heap, let $\perp$ be the auxiliary node that works as the parent of root and is connected
to root with an edge labeled with any symbol $c \in \Sigma \cup \{0\}$. We define $psp(root) = \perp$.

When $s$ is the active position in $PPH(t[1 : k])$, we call $prev(t[s : k])$ the active node. If no
node holds a secondary position, root becomes the active node and the active position is set
to $k + 1$. The nodes for the secondary positions $s, s + 1, \ldots, k$ can be visited by traversing
with the suffix pointers from the active node. Thus, the algorithm only has to memorize the
active position and the active node in order to visit any other secondary positions.

Updating $PPH(t[1 : k])$ to $PPH(t[1 : k + 1])$ specified by Lemma 8 is processed as the
following procedures. The algorithm traverses with the suffix pointers from the active node
till the node that has the outgoing edge labeled with $prev(t[i : k + 1])[k - i + 2]$ is found,
which is $i = r$. For each traversed node, a new node is created and linked by an edge
labeled with $prev(t[i : k + 1])[k - i + 2]$ to each node. A suffix pointer to this new node is
set from the previously created node. When the node that has the outgoing edge labeled
with $prev(t[i : k + 1])[k - i + 2]$ is traversed, the algorithm moves to the node that is led to
by this edge, and a suffix pointer to this node is set from the last created node, then the
algorithm assigns this node to be the active node.

A pseudocode of our proposed construction algorithm is given as Algorithm 1. $prim(v)$ and
$sec(v)$ denotes primary and secondary positions of $v$, respectively. From the property of prev-
encoding, $prev(t[i + 1 : k + 1])[k - i + 1] = prev(t[i : k + 1])[k - i + 2]$ if $prev(t[i : k + 1])[k - i + 2] \in \Sigma$ or $prev(t[i : k + 1])[k - i + 2] \leq k - i$ and $prev(t[i + 1 : k])[k - i + 1] = 0$ otherwise.
Therefore, we use a function $normalize(c, j)$ that returns $c$ if $c \in \Sigma$ or $c \leq j$ and returns $0$
otherwise.

The construction algorithm consists of $n$ iterations. In the $i$-th iteration, the algorithm
read $t[i]$ and make $PPH(t[1 : i])$. In the $i$-th iteration, the traversal of the suffix pointers as
explained above is done. Since the depth of the current node decreases by traversing a suffix
pointer, the number of the nodes that can be visited by traversal is $O(n)$. For each traversed
node, all the operations such as creating a node, an edge and updating position can be done
in $O(\log (|\Sigma| + |\Pi|))$. Therefore, the total time for the traversals is $O(n \log (|\Sigma| + |\Pi|))$.

From the above discussion, the following theorem is obtained.

$\triangleright$ **Theorem 10.** Given $t \in (\Sigma \cup \Pi)^n$, Algorithm 1 constructs $PPH(t)$ in $O(n \log (|\Sigma| + |\Pi|))$
time and space.
Algorithm 1: Parameterized position heap online construction algorithm

**Input:** A p-string \( t \in (\Sigma \cup \Pi)^n \)

**Output:** A parameterized position heap \( PP\text{H}(t) \)

1. create root and \( \bot \) nodes;
2. \( psp(root) = \bot \);
3. \( child(\bot, c) = root \) for \( c \in \Sigma \cup \{0\} \);
4. currentNode = root;
5. \( s = 1 \);
6. for \( i = 1 \) to \( n \) do
7. \( c = \text{normalize}(\text{prev}(t)[i], \text{depth(currentNode)}) \);
8. lastCreateNode = undefined;
9. while \( child(currentNode, c) = \text{null} \) do
10. create newnode;
11. prim(newnode) = \( s \);
12. child(currentNode, c) = newnode;
13. if lastCreateNode \neq \text{undefined} then \( psp(lastCreateNode) = \text{newnode} \);
14. lastCreateNode = newnode;
15. currentNode = psp(currentNode);
16. \( c = \text{normalize}(\text{prev}(t)[i], \text{depth(currentNode)}) \);
17. \( s = s + 1 \);
18. currentNode = child(currentNode, c);
19. if lastCreateNode \neq \text{undefined} then \( psp(lastCreateNode) = \text{currentNode} \);
20. while \( s \leq n \) do
21. sec(currentNode) = \( s \);
22. currentNode = psp(currentNode);
23. \( s = s + 1 \);

4.3 Augmented Parameterized Position Heaps

We will describe augmented parameterized position heaps, the parameterized position heaps with an additional data structure called the parameterized maximal-reach pointers similar to the maximal-reach pointers for the position heap [8]. The augmented parameterized position heap gives an efficient algorithm for parameterized pattern matching.

**Definition 11 (Parameterized Maximal-Reach Pointer).** For a position \( i \) on \( t \), a parameterized maximal-reach pointer of \( \text{pmrp}(i) \) is a pointer from node \( i \) to the deepest node whose path label is a prefix of \( \text{prev}(t[i:]) \).

Obviously, if \( i \) is a secondary position, then \( \text{pmrp}(i) \) is node \( i \) itself. We assume that the parameterized maximal-reach pointer for a double node applies to the primary position of this node. Figure 2 (b) shows an example of an augmented parameterized position heap. Given a prev-encoded p-string \( \text{prev}(w) \) represented in an augmented parameterized position heap \( \text{APPH}(t) \) and a position \( 1 \leq i \leq n \), we can determine whether \( \text{prev}(w) \) is a prefix of \( \text{prev}(t[i:]) \) or not in \( O(1) \) time by checking whether \( \text{pmrp}(i) \) is a descendant of \( \text{prev}(w) \) or not. It can be done in \( O(1) \) time by appropriately preprocessing \( \text{APPH}(t) \) [5].

Parameterized maximal-reach pointers can be computed by using parameterized suffix pointers, similar to [13]. Algorithm 2 shows an algorithm to compute parameterized maximal-reach pointers. \( \text{pmrp}(i) \) is computed iteratively for \( i = 1, 2, \ldots, n \). Assume that we have computed \( \text{pmrp}(i) \) for some \( i \). Let \( \text{pmrp}(i) = \text{prev}(t[i:]) \). Obviously, \( \text{prev}(t[i + 1:]) \) is a...
4.4 Parameterized Pattern Matching with Augmented Parameterized Position Heaps

Ehrenfeucht et al. [8] and Kucherov [13] split a pattern \( p \) into segments \( q_1, q_2, \ldots, q_k \), then compute occurrences of \( q_1q_2\cdots q_k \) iteratively for \( j = 1, \ldots, k \). The correctness depends on a simple fact that for strings \( x = tl[i : i + |x| - 1] \) and \( y = tl[i + |x| : i + |x| + |y| - 1] \) implies \( xy = tl[i : i + |xy| - 1] \). However, when \( x, y, \) and \( t \) are p-strings, \( \text{prev}(x) = \text{prev}(tl[i : i + |x| - 1]) \) and \( \text{prev}(y) = \text{prev}(tl[i + |x| : i + |x| + |y| - 1]) \) does not necessarily implies \( \text{prev}(xy) = \text{prev}(tl[i : i + |xy| - 1]) \). Therefore, we need to modify the matching algorithm for parameterized strings.

Let \( x, y \) and \( w \) be p-strings such that \(|w| = |xy|\), \( \text{prev}(x) = \text{prev}(w[|x|]) \) and \( \text{prev}(y) = \text{prev}(w[|x| + 1 : ]) \). Let us consider the case that \( \text{prev}(xy) \neq \text{prev}(w) \). From \( \text{prev}(x) = \text{prev}(w[|x|]) \) and \( \text{prev}(y) = \text{prev}(w[|x| + 1 : ]) \), \( x \) and \( y \) have the same structure of \( w[|x|] \) and \( w[|x| + 1 : ] \), respectively. However, the parameter symbols those are prev-encoded into \( 0 \) in \( \text{prev}(y) \) and \( \text{prev}(w[|x| + 1 : ]) \), might be encoded differently in \( \text{prev}(xy) \) and \( \text{prev}(w) \), respectively. Therefore, we need to check whether \( \text{prev}(xy)[|x| + i] = \text{prev}(w)[|x| + i] \) if \( \text{prev}(y)[i] = 0 \). Given \( \text{prev}(xy) \) and the set of positions of \( 0 \) in \( \text{prev}(y), \ Z = \{ i \mid 1 \leq i \leq |y| \text{ such that } \text{prev}(y)[i] = 0 \} \). We need to verify whether \( \text{prev}(xy)[|x| + i] = \text{prev}(w)[|x| + i] \) or not for \( i \in \mathbb{Z} \). Since the size of \( \mathbb{Z} \) is at most \(|\Pi|\), this computation can be done in \( O(|\Pi|) \) time.

Algorithm 2: Augmented parameterized position heap construction algorithm

Input: A p-string \( t \in (\Sigma \cup \Pi)^n \) and \( \text{PPH}(t) \)

Output: An augmented parameterized position heap \( \text{APPH}(t) \)

1. let \( t[n+1] = \$ \) where \( \$ \) is a symbol that does not appear in \( t \) elsewhere;
2. \( \text{currentNode} = \text{root} \);
3. \( l = 1; \)
4. for \( i = 1 \) to \( n \) do
5. \hspace{1em} \( c = \text{normalize}(\text{prev}(t)[i], l - i); \)
6. \hspace{1em} while \( \text{child}(\text{currentNode}, c) \neq \text{null} \) do
7. \hspace{2em} \( \text{currentNode} = \text{child}(\text{currentNode}, c); \)
8. \hspace{1em} \( l = l + 1; \)
9. \hspace{1em} \( c = \text{normalize}(\text{prev}(t)[i], l - i); \)
10. \( \text{pmrp}(i) = \text{currentNode}; \)
11. \( \text{currentNode} = \text{psp}(\text{currentNode}); \)

prefix of the string represented by \( \text{pmrp}(i + 1) \). Thus, in order to compute \( \text{pmrp}(i + 1) \), we should extend the prefix \( \text{prev}(t[i + 1 : l]) = \text{psp}(\text{prev}(t[i : l])) \) in \( \text{PPH}(t) \) until we found \( l' \) such that node \( \text{prev}(t[i + 1 : l']) \) does not have outgoing edge labeled with \( \text{prev}(t[i + 1 : ]) [l' - i + 1] \) \( \text{and \ set \ \text{pmrp}(i + 1) = \text{prev}(t[i + 1 : l']). \end{align*} \) In this time, we need re-compute \( \text{prev}(t[i + 1 : ]) \) by replacing \( \text{prev}(t[i + 1 : ]) [j] \) with \( 0 \) if we found that \( \text{prev}(t[i + 1 : ]) [j] \geq j \). The total number of extending \( \text{prev}(t[i + 1 : l]) \) in the algorithm is at most \( n \) because both \( i \) and \( l \) always increase in each iteration. In each iteration, operations such as traversing a child node can be done in \( O(\log(|\Sigma| + |\Pi|)) \). Therefore, we can get the following theorem.

\[ \textbf{Theorem 12. Parameterized maximal-reach pointers for PPH}(t) \text{ can be computed in } O(n \log(|\Sigma| + |\Pi|)) \text{ time.} \]
Algorithm 3: Parameterized pattern matching algorithm with APPH

**Input:** \( t \in (\Sigma \cup \Pi)^n \), \( p \in (\Sigma \cup \Pi)^m \), and \( \text{APPH}(t) \)

**Output:** The list \( \text{ans} \) of position \( i \) such that \( \text{prev}(p) = \text{prev}(t[i : i + m - 1]) \)

1. let \( w \) be the longest prefix of \( \text{prev}(p) \) represented in \( \text{APPH}(t) \) and \( u \) be the node represents \( w \);
2. if \( |w| = m \) then
   1. \( v = \text{root} \);
   2. for \( i = 1 \) to \( m \) do
      1. \( v = \text{child}(v, \text{prev}(p)[i]) \);
      2. if \( \text{pmrp}(u) \in \text{Des}_{\text{APPH}(t)}(u) \) then add \( \text{prim}(v) \) to \( \text{ans} \);
   3. add all primary and secondary position of descendants of \( u \) to \( \text{ans} \);
3. else
   1. \( v = \text{root} \);
   2. \( i = 1, j = 1 \);
   3. while \( i \leq |w| \) do
      1. \( v = \text{child}(v, \text{prev}(p)[i]) \);
      2. \( i = i + 1 \);
      3. if \( \text{pmrp}(v) = u \) then add \( \text{prim}(v) \) to \( \text{ans} \);
   4. while \( i \neq m \) do
      1. \( j = i, v = \text{root} \);
      2. \( Z = \text{empty list} \);
      3. while \( i \neq m \) do
         1. \( c = \text{normalize}(\text{prev}(p)[i], i - j) \);
         2. if \( \text{child}(v, c) = \text{null} \) then \( \text{break} \);
         3. if \( c = 0 \) then add \( i \) to \( Z \);
         4. \( v = \text{child}(v, c) \);
         5. \( i = i + 1 \);
      4. if \( v = \text{root} \) then \text{return} \( \text{empty list} \);
   5. foreach \( i' \in \text{ans} \) do
      1. if \( i = m \) then
         1. if \( \text{pmrp}(i' + j - 1) \not\in \text{Des}_{\text{APPH}(t)}(v) \) then \text{remove} \( i' \) from \( \text{ans} \);
      2. else
         1. if \( \text{pmrp}(i' + j - 1) \neq v \) then \text{remove} \( i' \) from \( \text{ans} \);
         2. for \( k = 1 \) to \( |Z| \) do
            1. if \( \text{normalize}(\text{prev}(t)[i' + Z[k] - 1], Z[k] - 1) \neq \text{prev}(p)[Z[k]] \) then
               1. remove \( i' \) from \( \text{ans} \);
   6. \text{return} \( \text{ans} \);

A pseudocode of proposed matching algorithm for the parameterized pattern matching problem is shown in Algorithm 3. \( \text{Des}_{\text{APPH}(t)}(u) \) denotes the set of all descendants of node \( u \) in \( \text{APPH}(t) \) including node \( u \) itself. The occurrences of \( p \) in \( t \) have the following properties on \( \text{APPH}(t) \).

**Lemma 13.** If \( \text{prev}(p) \) is represented in \( \text{APPH}(t) \) as a node \( u \) then \( p \) occurs at position \( i \) iff \( \text{pmrp}(i) \) is \( u \) or its descendant.

**Proof.** Let \( u \) be a node represents \( \text{prev}(p) \). Assume \( p \) occurs at position \( i \) in \( t \) and represented in \( \text{APPH}(t) \) as \( \text{prev}(t[i : k]) \). Since either \( \text{prev}(t[i : k]) \) is a prefix of \( \text{prev}(p) \) or \( \text{prev}(p) \) is a prefix of \( \text{prev}(t[i : k]) \), then \( i \) is either an ancestor or descendant of \( u \). For both cases \( \text{pmrp}(i) \) is a descendant of \( u \), because \( p \) occurs at position \( i \).
Next let $i$ be a node such that $pmrp(i)$ is a descendant of $u$ and represents $prev(t[i : k])$. In this case, $prev(p)$ is a prefix of $prev(t[i : k])$. Therefore $p$ occurs at $i$.

**Lemma 14.** Assume $prev(p)$ is not represented in $APPH(t)$. We can split $p$ into $q_1, q_2, \ldots, q_k$ such that $q_j$ is the longest prefix of $prev(p[|q_1 \cdots q_{j-1}| + 1 :])$ that is represented in $APPH(t)$. If $p$ occurs at position $i$ in $t$, then $pmrp(i + |q_1 \cdots q_{j-1}|)$ is the node $prev(q_j)$ for $1 \leq j < k$ and $pmrp(i + |q_1 \cdots q_{k-1}|)$ is the node $prev(q_k)$ or its descendant.

**Proof.** Let $p = q_1 q_2 \cdots q_k$ occurs at position $i$ in $t$. Since $prev(q_1)$ is a prefix of $prev(p)$, then $pmrp(i)$ is the node that represents $prev(q_1)$ or its descendant. However, if $pmrp(i)$ is a descendant of node $prev(q_1)$, then we can extend $q_1$ which contradicts with the definition of $q_1$. Therefore, $pmrp(i)$ is the node represents $prev(q_1)$.

Similarly for $1 < j < k$, $prev(q_j)$ is a prefix of $prev(p[|q_1 \cdots q_{j-1}| + 1 :])$ and occurs at position $i + |q_1 \cdots q_{j-1}|$ in $t$. Therefore, $pmrp(i + |q_1 \cdots q_{j-1}|)$ is the node represents $prev(q_j)$. Last, since $q_k$ is a suffix of $p$, then $pmrp(i + |q_1 \cdots q_{j-1}|)$ can be the node $prev(q_k)$ or its descendant.

Algorithm 3 utilizes Lemmas 13 and 14 to find occurrences of $p$ in $t$ by using $APPH(t)$. First, if $prev(p)$ is represented in $APPH(t)$ then the algorithm will output all position $i$ such that $pmrp(i)$ is a node $prev(p)$ or its descendant. Otherwise, it will split $p$ into $q_1 q_2 \cdots q_k$ and find their occurrences as described in Lemma 14. The algorithm also checks whether $prev(q_1 \cdots q_j)$ occurs in $t$ or not in each iteration as described the above.

Examples of parameterized pattern matching by using an augmented position heap are given in Figure 4. Let $t = xaxyxyxyxxyxyxy$ be the text. In Figure 4 (a) we want to find the occurrence positions of a pattern $p_1 = xxyxy$ in $t$. In this case, since $prev(p_1) = 0022$ is represented in $PPH(t)$, The algorithm outputs all positions $i$ such that $pmrp(i)$ is the node 0022 or its descendants, those are 3, 4, 5, and 11. On the other hand, Figure 4 (b) shows how to find the occurrence positions of a pattern $p_2 = ayx$ in $t$. In this case, $prev(p_2) = a002$ is not represented in $PPH(t)$. Therefore, the algorithm finds the longest prefix of $prev(p_2)$ that is represented in $PPH(i)$, which is $prev(p_2)[1 : 2] = a0$. We can see that $pmrp(2) = pmrp(10) = a0$, then we save positions 2 and 10 as candidates to $ans$. Next, The algorithm finds the node that represents the longest prefix of $prev(p_2[3 :]) = 00$ which is $prev(p_2[3 :]) = 00$ itself. Since both of $pmrp(2 + |p_2[1 : 2]|) = pmrp(4)$ and $pmrp(10 + |p_2[1 : 2]|) = pmrp(12)$ are descendants of the node 00, $prev(t[2 : 5][3]) = prev(t[10 : 13][3]) = prev(p_2)[3] = 0$, and $prev(t[2 : 5][4]) = prev(t[10 : 13][4]) = prev(p_2)[4] = 2$, then the algorithm outputs 2 and 10.

![Figure 4](image-url) Examples of finding occurrence positions of a pattern using an augmented parameterized position heap $PPH(xaxyxyxyxxyxyxy)$. (a) Finding $xxyxy$ ($prev(xxyxy) = 0022$). (b) Finding $ayx$ ($prev(ayx) = a002$).
The time complexity of the matching algorithm is as follow.

**Theorem 15.** Algorithm 3 runs in $O(m \log (|\Sigma| + |\Pi|) + m|\Pi| + occ)$ time.

**Proof.** It is easily seen that we can compute line 4 to 7 in $O(m \log (|\Sigma| + |\Pi|) + occ)$ time. Assume that $p$ can be decomposed into $q_1, q_2, \cdots, q_k$ such that $q_1$ is the longest prefix of $p$ and $q_i$ is the longest prefix of $\text{prev}(p[q_1 \cdots q_{i-1}] + 1 :]$ represented in $\text{APPH}(t)$. The loop for line 15 consists of $k - 1$ iterations. In the loop line 18 in $j$-th iteration, $q_{j+1}$ is extended up to reach $|q_{j+1}|$ length. This can be computed in $O(|q_{j+1}| \log (|\Sigma| + |\Pi|))$ time. After $k - 1$ iterations, the total number of extending of $q_{j+1}$ does not exceed $m$, because $\sum_{j=2}^{k}|q_j| < m$. In the loop for line 25, the algorithm verifies elements of $\text{ans}$. In $j$-th iteration, the size of $\text{ans}$ is at most $|q_j|$. Thus, after $k - 1$ iterations, the total number of elements verified in line 25 does not exceed $m$ by the same reason for that of line 18. In each verification in line 25, the number of checks for line 27 and 29 is at most $|q_j|$. Therefore, it can be computed from line 25 to 32 in $O(m|\Pi|)$ time.

## 5 Conclusion and Future Work

For the parameterized pattern matching problem, we proposed an indexing structure called a parameterized position heap. Given a p-string $t$ of length $n$ over a constant size alphabet, the parameterized position heap for $t$ can be constructed in $O(n \log (|\Sigma| + |\Pi|))$ time by our construction algorithm. We also proposed an algorithm for the parameterized pattern matching problem. It can be computed in $O(m \log (|\Sigma| + |\Pi|) + m|\Pi| + occ)$ time using parameterized position heaps with parameterized maximal-reach pointers. Gagie et al. [10] showed an interesting relationship between position heap and suffix array of a string. We will examine this relation for parameterized position heap and parameterized suffix array [7, 12] as a future work.

Abstract

Pattern matching on a set of similar texts has received much attention, especially recently, mainly due to its application in cataloguing human genetic variation. In particular, many different algorithms have been proposed for the \textit{off-line} version of this problem; that is, constructing a compressed index for a set of similar texts in order to answer pattern matching queries efficiently. However, the \textit{on-line}, more fundamental, version of this problem is a rather undeveloped topic. Solutions to the on-line version can be beneficial for a number of reasons; for instance, efficient on-line solutions can be used in combination with partial indexes as practical trade-offs. We make here an attempt to close this gap via proposing two efficient algorithms for this problem. Notably, one of the algorithms requires time linear in the size of the texts’ representation, for short patterns. Furthermore, experimental results confirm our theoretical findings in practical terms.

1 Introduction

It is possible to represent closely related sequences that have been aligned using a multiple sequence alignment (MSA) algorithm into one compacted form, that is able to represent the non-polymorphic sites (columns) of the MSA, as well as the polymorphic ones [10]. This representation compresses maximal sequences of non-polymorphic sites, while the polymorphic ones, containing substitutions, insertions, and deletions of letters, are represented as a set containing all possible variants observed at that location. Consider, for instance, the following:

\[
\begin{align*}
\text{ATGCAACGGGT} & \quad \text{TA} \quad \text{TATA} \\
\text{ATGCAACGGGTTATTTT} & \\
\text{ATGCACTGGG} & \quad \text{TATA} \\
\end{align*}
\]

These sequences can be compacted into a single string \( \tilde{T} \) containing some deterministic and some non-deterministic segments. Note that a non-deterministic segment is a finite set of deterministic strings and may contain an empty string \( \varepsilon \) corresponding to a deletion. The total number of segments is the length of \( \tilde{T} \) and the total number of letters is the size of \( \tilde{T} \).

\[
\tilde{T} = \{ \text{ATGCA} \} \cdot \{ \begin{array}{c} \text{A} \\ \text{C} \end{array} \} \cdot \{ \begin{array}{c} \text{G} \\ \text{T} \end{array} \} \cdot \{ \begin{array}{c} \text{GG} \end{array} \} \cdot \{ \begin{array}{c} \text{TATA} \\ \text{TATA} \\ \varepsilon \end{array} \} \cdot \{ \text{TTTTA} \}
\]

This representation has been defined in [11] as an elastic-degenerate text. The natural problem that arises is finding all matches of a deterministic pattern \( P \) in text \( \tilde{T} \). We call this the ELASTIC-DEGENERATE STRING MATCHING (EDSM) problem. The simplest version of this problem assumes that a degenerate segment can contain only single letters [9].

An elastic-degenerate text can represent, for example, a set of closely-related DNA sequences. For instance, a pan-genome [18, 24, 12, 21] is a reference sequence which is not just a single genome, but the result of an MSA of several of them that share large consensus regions and also exhibit differences at some positions. Recently, various data structures to store pan-genomes have been suggested [8, 4]. In particular, due to the application of cataloguing human genetic variation [23], there has been ample work in the literature on the off-line (indexing) version of the pattern matching problem [10, 14, 22, 15, 16]. In literature, there are also algorithms and applications for the problem of inferring motifs from degenerate input texts [20, 19]. However, to the best of our knowledge, the on-line, more fundamental, version of the EDSM problem has not been studied as much as indexing approaches. Solutions to the on-line version can be beneficial for a number of reasons: (a) efficient on-line solutions can be used in combination with partial indexes as practical trade-offs; (b) efficient on-line solutions for exact pattern matching can be applied for fast average-case approximate pattern matching, similar to standard strings [3]; (c) on-line solutions can be useful when one wants to search for a set of patterns in elastic-degenerate texts, similar to standard strings [1, 2].

Our Contributions. Let us denote by \( m \) the length of pattern \( P \), by \( n \) the length of \( \tilde{T} \), and by \( N > m \) the size of \( \tilde{T} \) (see Section 2 for definitions). In [11], an algorithm for solving the EDSM problem in time \( \mathcal{O}(\alpha\gamma mn + N) \) and space \( \mathcal{O}(N) \) was presented; where \( \alpha \) and \( \gamma \) are parameters, respectively representing the maximum number of strings in any degenerate
segment of the text and the maximum number of degenerate segments spanned by any occurrence of the pattern in the text. In this paper, we improve the state-of-the-art; we present two new algorithms to solve the same problem in an on-line manner. The first one requires time $O(m^2 + N)$ after a preprocessing stage with time and space $O(m)$; the second algorithm requires time $O(N \cdot \lceil \frac{m}{w} \rceil)$ after a preprocessing stage with time and space $O(m \cdot \lceil \frac{m}{w} \rceil)$, where $w$ is the size of the computer word in the RAM model. Thus, the second algorithm requires time linear in the size of the texts’ representation, for short patterns. Finally, we present experiments confirming our theoretical findings in practical terms.

2 Definitions

We begin with a few definitions, generally following [5]. An alphabet $\Sigma$ is a non-empty finite set of letters of size $|\Sigma|$. A (deterministic) string on a given alphabet $\Sigma$ is a finite sequence of letters of $\Sigma$. For this work, we assume that the alphabet is fixed, i.e. $|\Sigma| = O(1)$. The length of a string $x$ is denoted by $|x|$. For two positions $i$ and $j$ on $x$, we denote by $x[i..j] = x[i]..x[j]$ the factor (sometimes called substring) of $x$ that starts at position $i$ and ends at position $j$ (it is empty if $j < i$), and by $\varepsilon$ we denote the empty string. The set of all strings on an alphabet $\Sigma$ (including the empty string $\varepsilon$) is denoted by $\Sigma^*$. For any string $y = uxx$, where $u$ and $v$ are strings, if $u = \varepsilon$ then $x$ is a prefix of $y$. Similarly, if $v = \varepsilon$ then $x$ is a suffix of $y$. We say that $x$ is a proper factor (resp. prefix/suffix) of $y$ if $x$ is a factor (resp. prefix/suffix) of $y$ distinct from $y$. By $B_{u,v}$ we denote the set containing all indices $i$, such that the prefix $u[0..i]$ of string $u$ is also a suffix of string $v$.

Example 1. Suppose we have two strings $u = ATATG$ and $v = CATAT$. Then $B_{u,v} = \{1, 3\}$ because of prefix/suffix AT and prefix/suffix ATAT, respectively.

An elastic-degenerate string (ED string) $\tilde{X} = \tilde{X}[0], \tilde{X}[1], \ldots, \tilde{X}[n-1]$, of length $n$, on an alphabet $\Sigma$, is a finite sequence of degenerate letters. Every degenerate letter $\tilde{X}[i]$, for all $0 \leq i < n$, is a non-empty set of strings $\tilde{X}[i][j]$, with $0 \leq j < |\tilde{X}[i]|$, where each $\tilde{X}[i][j]$ is a deterministic string on $\Sigma$. The total size of $\tilde{X}$ is defined as

$$N = \sum_{i=0}^{n-1} \sum_{j=0}^{|\tilde{X}[i][j]|} |\tilde{X}[i][j]|.$$

Only for the purpose of computing $N$, $|\varepsilon| = 1$. We remark that, for an ED string $\tilde{X}$, the size and the length are two distinct concepts (see Example 2).

We say that a string $Y$ matches an ED string $\tilde{X} = \tilde{X}[0], \ldots, \tilde{X}[m' - 1]$ of length $m' > 1$, denoted by $Y \approx \tilde{X}$, if and only if string $Y$ can be decomposed into $y_0 \ldots y_{m'-1}$, where each $y_i \in \Sigma^*$, such that:

1. there exists a string $s \in \tilde{X}[0]$ such that a suffix of $s$ is $y_0 \neq \varepsilon$;
2. if $m' > 2$, there exists $s \in \tilde{X}[i]$, for all $1 \leq i \leq m' - 2$, such that $s = y_i$;
3. there exists a string $s \in \tilde{X}[m' - 1]$ such that a prefix of $s$ is $y_{m'-1} \neq \varepsilon$.

Note that, in the above definition, we require that both $y_0$ and $y_{m'-1}$ are non-empty to avoid spurious matches at the beginning or end of an occurrence. A string $Y$ is said to have an occurrence ending at position $j$ in an ED string $\tilde{T}$ if there exist $i < j$ such that $\tilde{T}[i] \ldots \tilde{T}[j] \approx Y$, or, if there exists $s \in \tilde{T}[j]$ such that $Y$ occurs in $s$.

Example 2 (Running example). Suppose we have a pattern $P = ACACA$, of length $m = 5$, and an ED string $\tilde{T}$, of length $n = 6$ and size $N = 18$; the first occurrence of $P$ starts at...
position 1 and ends at position 2 of $\tilde{T}$; and the second one starts at position 2 and ends at position 4.

$$\tilde{T} = \{ \text{C} \} \cdot \{ \text{A} \text{C} \} \cdot \{ \text{AC} \text{ACC} \text{CACA} \} \cdot \{ \text{C} \text{A} \text{C} \} \cdot \{ \text{A} \text{C} \} \cdot \{ \text{C} \}$$

We are now in a position to formally define the main problem of this paper.

**Algorithmic Tools**

The suffix tree $ST_y$ of a string $y$, of length $n > 0$, is a compact trie representing all suffixes of $y$. The nodes of the trie which become nodes of the suffix tree are called explicit nodes, while the other nodes are called implicit. Each edge of the suffix tree can be viewed as an upward maximal path of implicit nodes starting with an explicit node. Moreover, each node belongs to a unique path of that kind. Thus, each node of the trie can be represented in the suffix tree by the edge it belongs to and an index within the corresponding path. We let $\mathcal{P}(v)$ denote the path-label of a node $v$, that is, the concatenation of the edge labels along the path from the root to $v$. We say that $v$ is path-labelled $\mathcal{P}(v)$. Node $v$ is marked as a terminal node if its path-label is a suffix of $y$, that is, $\mathcal{P}(v) = y[i..n-1]$ for some $0 \leq i < n$. Note that $v$ is also labelled with index $i$. Thus, each factor of $y$ is uniquely represented by an explicit or an implicit node of $ST_y$. More details on suffix trees can be found in [7, 5].

**Fact 3 ([6, 5]).** Given a string $y$ of length $n$, $ST_y$ can be constructed in time and space $O(n)$. Finding all $\text{Occ}_y$ occurrences of a string $x$, of length $m$, in $y$ can be performed in time $O(m + \text{Occ}_y)$ using $ST_y$.

A border of a non-empty string $x$ is a proper factor of $x$ that is both a prefix and a suffix of $x$. We introduce the function $\text{border}(x)$ defined for every non-empty string $x$ as the longest border of $x$. Let $x$ be a string of length $m \geq 1$. We define the border table $B$: $\{0, 1, \ldots, m - 1\} \rightarrow \{0, 1, \ldots, m - 1\}$ by $B[k] = \text{border}(x[0..k])$, for $k = 0, 1, \ldots, m - 1$.

**Fact 4 ([113, 5]).** Given a string $x$ of length $m$, the border table of $x$ can be computed on-line in time $O(m)$. All borders of $x$ can be specified within the same time complexity using the border table.

We remark that the border table and the notion of border refer to a proper prefix and a proper suffix of the same string, whereas the indexes in set $B_{x,y}$ refer to a string which is a prefix of a string ($x$) and a suffix of another ($y$), and that is not necessarily proper.

**Lemma 5.** Given a string $x$, of length $m$, and the suffix tree $ST_y$ of a string $y$, of length $n$, $B_{x,y}$ can be computed in time $O(m)$.

**Proof.** By applying Fact 3, we traverse $ST_y$ to find the terminal node $v$ corresponding to the longest prefix of $x$, which is path-labelled $\mathcal{P}(v)$. While traversing $ST_y$ with $x$, we add index $n - i - 1$ to $B_{x,y}$ if we encounter a terminal node $u$, such that $\mathcal{P}(u) = y[i..n-1]$. The longest such prefix of $x$ is of length at most $m$. No longer prefix of $x$ can be a suffix of $y$ as it does not occur in $y$. □
4 Algorithm

An ED string can always represent an exponential number of strings (per ending position), where the exact number is the product of the number of deterministic strings at previous positions. Searching a pattern in all these strings separately is thus not acceptable.

Main idea. Our algorithm has a preprocessing phase where we build the suffix tree of the pattern \( P \) (Line 2 in pseudocode below). Then, in an on-line manner, we scan \( \tilde{T} \) from left to right and, for each \( \tilde{T}[i] \), we:

1. memorise the prefixes of the pattern that occur as suffixes of some \( s \in \tilde{T}[i] \) (Lines 5 & 12 in pseudocode);
2. check whether at \( \tilde{T}[i] \) it is possible to extend a partial occurrence of the pattern which has started earlier in the ED text (Lines 13 – 16 in pseudocode);
3. in both previous cases we finally check whether a full occurrence of \( P \) actually also ends in \( \tilde{T}[i] \) (Lines 6 – 8 & 17 – 22 in pseudocode).

We perform these steps by computing and storing, for each \( 0 \leq i < n \), the list \( L_i \) of the rightmost positions of prefixes of \( P \) that occur at the end of \( \tilde{T}[i] \). Below, we formally present Algorithm EDSM that solves the EDSM in an on-line manner. Note that by \( \text{Insert}(A, L) \), we denote the operation that inserts the elements of a set \( A \) into a linked-list \( L \).

```plaintext
1 Algorithm EDSM(P, m, \tilde{T}, n)
2 Construct \( ST_P \);
3 \( L_0 \leftarrow \text{EmptyList}() \);
4 foreach \( S \in \tilde{T}[0] \) do
5    Compute \( B_{P,S} \) using the border table; \( \text{Insert}(B_{P,S}, L_0) \);
6    if \( |S| \geq m \) then
7       Search \( P \) in \( S \) using KMP and
8       report 0 if \( P \) occurs in \( S \) and \( \text{CheckDuplicate}(0) \);
9    \( L_i \leftarrow \text{EmptyList}() \);
10   foreach \( S \in \tilde{T}[i] \) do
11      Compute \( B_{P,S} \) using the border table; \( \text{Insert}(B_{P,S}, L_i) \);
12      if \( |S| < m \) then
13         Search \( S \) in \( P \) using \( ST_P \); denote starting positions by \( A \); 
14         foreach \( (p \in L_{i-1}, j \in A) \text{ such that } p + 1 = j \) do
15            \( \text{Insert}((p + |S|), L_i) \);
16      if \( |S| \geq m \) then
17         Search \( P \) in \( S \) using KMP and 
18         report \( i \) if \( P \) occurs in \( S \) and \( \text{CheckDuplicate}(i) \);
19         Compute \( B_{S,P} \) using \( ST_P \);
20         if there exists \( (p \in L_{i-1}, j \in B_{S,P}) \text{ such that } p + j + 2 = m \) then
21            Report \( i \) if \( \text{CheckDuplicate}(i) \);
```

Example 6 shows Steps (1) and (2) on the running example. The border table shown in Example 6 has to be computed for all text positions, leading to the overall complexity stated in Lemma 7.
Assume we have already computed \( L_0 \) and \( L_1 \), and we move to position \( i = 2 \), where at \( \tilde{T}[i] \) we have three strings \( \{S_0, S_1, S_2\} \), with \( S_0 = AC, S_1 = ACC, \) and \( S_2 = CACA \). We generate the string \( X_1 = X_2 = P \tilde{S}_0 S_0 S_1 S_2 S_2 = ACACAS_0ACCS_2CACA \) and build its border table \( B \) (Line 12 in pseudocode).

</table>

In order to compute \( B_{P,S} \) (Line 12), we read \( B[7] = 2 \), which gives the length of the longest string that is a prefix of \( P \) and a suffix of \( S_0 \). To check if there exist borders of length shorter than 2, we read \( B[2 - 1] = 0 \), indicating that no shorter border exists. Therefore, we have \( B_{P,S_0} = \{1\} \). We then read \( B[11] = 0 \), telling us that no prefix of \( P \) is a suffix of \( S_1 \), and hence \( B_{P,S_1} = \emptyset \). We read \( B[16] = 3 \), which gives the length of the longest string that is a prefix of \( P \) and a suffix of \( S_2 \). To check if there exist shorter borders, we read \( B[3 - 1] = 1 \), indicating that a shorter border of length 1 exists. Since \( B[1 - 1] = 0 \), no shorter border exists. Therefore, we have \( B_{P,S_2} = \{0, 2\} \). This gives us a partial \( \mathcal{L}_1 \) = \{0, 1, 2\} for position \( i = 2 \) that concludes Step 1 for position \( i = 2 \) (INSERT(\( B_{P,S_i} \), \( L_i \)), Line 12). Further on, at Step 2, we will add position 4 to \( \mathcal{L}_2 \) by extending the occurrence of \( P \) that had started at \( \tilde{T}[1] \). Putting everything together, we get \( \mathcal{L}_2 \) = \{0, 1, 2, 4\} (INSERT(\( \{p + |S|\}, L_i \)), Lines 15 – 16).

**Lemma 7.** Given \( P \), of length \( m \), and \( \tilde{T} \), of length \( n \) and size \( N \), the sets \( B_{P,S} \) with \( S \in \tilde{T}[i] \), for all \( i \in [0, n - 1] \), can be computed in time \( O(N) \).

**Proof.** For each position \( i \), we generate a string \( X_i = P \tilde{S}_0 S_0 S_1 S_2 \ldots S_{k-1} S_{k-1} \), where \( S_j \in \tilde{T}[i] \), \( 0 \leq j < k \), and \$’s are distinct letters not in \( \Sigma \). We build the border table \( B \) of string \( X_i \). By traversing \( B \) from left to right we can compute sets \( B_{P,S_j} \). Specifically, for any string \( S_j \), all borders that are suffixes of \( S_j \) and prefixes of \( P \) can be computed in time \( O(|S_j|) \), since there exist at most \( |S_j| \) such borders. By Fact 4, we can build all border tables, and hence compute all \( B_{P,S_j} \) for all \( S_j \in \tilde{T}[i] \), in time \( O(|P| + \sum_{j=1}^{k-1} |S_j|) \). Since the length and the total size of \( \tilde{T} \) are \( n \) and \( N \), respectively, sets \( B_{P,S_j} \) can be computed in time \( O(nm + N) \). By noting that the border table for \( P \) can be computed only once and that the border table computation can be done on-line (Fact 4), the whole computation is bounded by \( O(N) \). \( \blacksquare \)

**Lemma 8.** Given \( P \), \( S \tilde{T} \tilde{P} \), and \( \tilde{T} \), of length \( n \) and size \( N \), the sets \( B_{S,P} \), \( S \in \tilde{T}[i] \), for all \( i \in [1, n - 1] \), can be computed in time \( O(N) \).

**Proof.** By Lemma 5, for any \( S \in \tilde{T}[i] \), \( |S| \leq |P| \), \( B_{S,P} \) can be computed in time \( O(|S|) \) using \( S \tilde{T} \tilde{P} \). Since the total size of \( \tilde{T} \) is \( N \), sets \( B_{S,P} \) can be computed in time \( O(N) \). \( \blacksquare \)

**Lemma 9.** Lists \( \mathcal{L}_i \), for all \( i \in [0, n - 1] \), in Algorithm EDSM can be computed in time \( O(nm^2 + N) \).

**Proof.** List \( \mathcal{L}_0 \) consists of the elements of \( B_{P,S} \) for position 0, which by Lemma 7 can be done within time \( O(N) \). For pattern \( P \) of length \( m \), there exist at most \( \frac{m(m+1)}{2} \) factors. For the strings \( S_j \in \tilde{T}[i] \), \( |S_j| \leq m \), \( 0 \leq j < k \), we can find at most \( \frac{m(m+1)}{2} = O(m^2) \) occurrences in pattern \( P \). By Fact 3, finding all occurrences can be done in time \( \sum_{j=0}^{k-1} (|S_j| + O(\mathcal{C}_{S_j})) \), and this is bounded by \( O(nm^2 + N) \) for all positions \( i \). This is because, by definition, no \( S_j, S_{j'} \in \tilde{T}[i] \) exist such that \( S_j = S_{j'} \). Each occurrence can cause only one extension from
\( \mathcal{L}_{i-1} \) to \( \mathcal{L}_i \). To avoid duplicates in \( \mathcal{L}_i \), we need to check if there exist more than one prefix extensions ending at the same position. Each check can be done in constant time using a bit vector of size \( m \), which we set on only once per position \( i \). Therefore, we can extend the prefixes in time \( O(m^2) \) for each position \( i \), and in time \( O(nm^2) \) for the whole text \( \hat{T} \) of length \( n \). By Lemma 7, sets \( B_{P,S} \) corresponding to new prefixes of pattern \( P \) which are suffixes of \( \{S_0, S_1, \ldots, S_{k-1}\} \) at position \( \hat{T}[i] \) can be found in time \( O(N) \). Merging new prefixes with the prefixes extended from \( \mathcal{L}_{i-1} \) can be done in time \( O(m) \), since both are at most \( m \). Therefore, lists \( \mathcal{L}_i \), for all \( i \in [0, n-1] \), in EDSM can be computed in time \( O(nm^2 + N) \).

Example 10 shows Step (3) on our running example.

\textbf{Example 10 (Running example).} Let us consider again \( P = ACACA \) and \( \hat{T} \) of Example 2. For position \( i = 4 \), we have \( \mathcal{L}_3 = \{1, 3\} \) and we have to compute \( \mathcal{L}_4 \). For \( S_0 = A \), we have \( B_{A,ACACA} = \{0\} \) (Line 20), so for \( 3 \in \mathcal{L}_3 \), we have that \( 3 + 0 + 2 = 5 = m \) (Line 21). Hence, one occurrence of \( P \) has been found. Moreover, for \( S_1 = AC \), we have \( B_{AC,ACACA} = \{0, 1\} \) (Line 20), so for \( 3 \in \mathcal{L}_3 \), we have that \( 3 + 0 + 2 = 5 = m \) (Line 21). Therefore, another occurrence of \( P \) has been found at the same position.

Since Algorithm EDSM reports all positions \( i \) in \( \hat{T} \) where at least one occurrence of \( P \) ends, and since more than one occurrence may end at the same position (as in Example 10), we need to avoid duplications. To this end, we can use a simple operation to check whether the current position \( i \) has already been reported (\textsc{CheckDuplicate}(i), Lines 8, 19, & 22).

\textbf{Theorem 11.} Algorithm EDSM solves the EDSM problem in an on-line manner in time \( O(nm^2 + N) \). Algorithm EDSM requires preprocessing time and space \( O(m) \).

\textbf{Proof.} The correctness of the algorithm follows from the correctness of the KMP algorithm \cite{KMP} if \( |S| > m, S \in \hat{T}[i] \), and from the combination of Lemmas 8 and 9, if \( |S| \leq m \). By definition, we cannot have any other type of (ending) occurrence.

By Fact 3, the suffix tree \( ST_P \) can be computed in time and space \( O(m) \). By Lemma 9, lists \( \mathcal{L}_i \), for all \( i \in [0, n-1] \), can be computed in time \( O(nm^2 + N) \). By Lemma 8, sets \( B_{S,P} \) can be computed in time \( O(N) \). In case \( |S| < m \), we use \( \mathcal{L}_{i-1} \) and set \( B_{S,P} \) to find and report occurrence \( i \) in time \( O(m) \) using a bit vector of size \( m \), which we initialise only once per position \( i \). Finally, searching \( P \) in \( S \in \hat{T}[i] \), in case \( |S| \geq m \), can be done in time \( O(|S|) \) using the KMP algorithm \cite{KMP}, which is bounded by \( O(N) \) for \( \hat{T} \) of total size \( N \).

The algorithm reads a position \( i \) and reports whether \( i \) is an ending position of some occurrence of \( P \), before reading position \( i + 1 \). Therefore, Algorithm EDSM solves the EDSM problem in an on-line manner in time \( O(nm^2 + N) \), with preprocessing time and space \( O(m) \).

\section{Bit-Vector Algorithm}

We introduce here Algorithm EDSM-BV, a non-trivial bit-vector version of Algorithm EDSM.

\textbf{Main idea.} The main idea of this algorithm is to simulate the previous algorithm using bit-level operations to maintain linked-lists \( \mathcal{L} \) and do the matching. To this end, we also add a further preprocessing step to the suffix tree of the pattern. This augmented suffix tree allows us to retrieve a bit-vector representation of all occurrences of an \( S \in \hat{T}[i] \) in \( P \) in time linear in \( |S| \). With this structure, we can use bit-level operations to compute \( \mathcal{L}_i \) from \( \mathcal{L}_{i-1} \).

We maintain a bit vector \( B \) of size \( m \) initialised with 0’s, such that, for each position \( 0 \leq k < m, B[k] = 1 \) if and only if \( P[0 \ldots k] \) has an occurrence ending at the current position
of $\hat{T}$. For each letter $c \in \Sigma$, we construct a bit vector $I_c$ of size $m$ initialised with 0’s, such that for each position $0 < k < m - 1$, $I_c[k - 1] = 1$, if and only if $P[k] = c$. We construct the suffix tree of $P$, denoted by $ST_P$, and augment it with bit vectors of size $m$ initialised with 0’s for each explicit node as follows: for node $u$, we create bit vector $M_u$ such that $M_u[k - 1] = 1$, if and only if the factor $P(u)$ represented by node $u$ occurs at position $k$ in $P$, $0 < k < m - 1$. The occurrences of $P(u)$ can be found at terminal nodes in the subtree rooted at node $u$. We denote this augmented suffix tree of $P$ by $Occ-Vector_P$. We wish to answer the following type of on-line queries: given a string $\alpha$, if $\alpha$ is a factor of $P$, then $Occ-Vector_P(\alpha)$ finds the node $w$ in $ST_P$ which represents $\alpha$, and returns a pointer to the bit vector $M_w$, where $u$ is the first explicit node in the subtree rooted at $w$. Otherwise (if $\alpha$ is not a factor of $P$), $Occ-Vector_P(\alpha)$ returns a pointer to a bit vector consisting of $m$ 0’s. This operation can be trivially realised in time $O(|\alpha|)$. Note that both $I_c$ and $M_u$ are shifted one bit to the left with respect to the pattern position they refer to; this is just an optimisation that will save us a shift in the algorithm.

Below, we formally present Algorithm EDSM-BV that solves the EDSM problem in an on-line manner.

```plaintext
1 Algorithm EDSM-BV($P, m, \hat{T}, n, \Sigma$)
2    Construct $I_c$, for all $c \in \Sigma$, and $Occ-Vector_P$;
3    $B[0..m-1] \leftarrow 0$;
4    foreach $S \in \hat{T}[0]$ do
5        Compute $B_{P,S}$ using the border table;
6        foreach $b \in B_{P,S}$ do
7            $B[b] \leftarrow 1$;
8        if $|S| \geq m$ then
9            Search $P$ in $S$ using KMP and
10           report 0 if $P$ occurs in $S$ and $CheckDuplicate(0)$;
11    foreach $i \in [1, n - 1]$ do
12        $B_1[0..m-1] \leftarrow 0$;
13        foreach $S \in \hat{T}[i]$ do
14            Compute $B_{P,S}$ using the border table;
15            foreach $b \in B_{P,S}$ do
16                $B_1[b] \leftarrow 1$;
17            if $|S| < m$ then
18                $B_2 \leftarrow B \& Occ-Vector_P(S)$;
19                $B_3 \leftarrow B_1 | (B_2 \gg |S|)$;
20            if $|S| \geq m$ then
21                Search $P$ in $S$ using KMP and
22                report $i$ if $P$ occurs in $S$ and $CheckDuplicate(i)$;
23                $B_3 \leftarrow B$;
24            foreach $j \in [0, \min\{|S|, m - 1\} - 1]$ do
25                $B_3 \leftarrow B_3 \& I_{S[j]}$;
26                $B_3 \leftarrow B_3 \gg 1$;
27                if $B_3[m - 1] = 1$ then
28                    Report $i$ if $CheckDuplicate(i)$;
29                $B \leftarrow B_1$;
```

In Algorithm EDSM-BV, at each iteration $i$, $\hat{T}[i]$ is processed (Lines 11 – 29) and, at the end, vector $B$ stores indexes $k$ such that $P[0..k]$ ends at position $i$. 
Lemma 12. Bit vectors \( I_c \), for all \( c \in \Sigma, \sigma = |\Sigma| \), can be constructed in time \( O(m + \sigma \cdot \lceil \frac{m}{\sigma} \rceil) \) and space \( O(\sigma \cdot \lceil \frac{m}{\sigma} \rceil) \). \( \text{Occ-Vector}_P \) can be constructed in time and space \( O(m \cdot \lceil \frac{m}{\sigma} \rceil) \).

Proof. For the bit vectors \( I_c \), we first read the alphabet and construct \( \sigma \) bit vectors of size \( m \) initialised with 0’s. Then we only need to read the pattern once, and for each position \( 0 < k < m - 1 \) in the pattern such that \( P[k] = c \), we set \( I_c[k-1] = 1 \). Reading the pattern once and setting \( I_c \) costs time \( O(m) \), so in total we need time \( O(m + \sigma \cdot \lceil \frac{m}{\sigma} \rceil) \) for the bit vectors \( I_c \). The space for each bit vector of size \( m \) is \( O(\lceil \frac{m}{\sigma} \rceil) \), so in total \( O(\sigma \cdot \lceil \frac{m}{\sigma} \rceil) \) space is required.

By Fact 3, \( ST_P \) can be constructed in time and space \( O(m) \). We traverse \( ST_P \) and allocate a bit vector \( M_u \) of size \( m \) initialised with 0’s for every explicit node \( u \) we visit. If \( u \) is a terminal node representing suffix \( P[k..m-1] \), we set \( M_u[k-1] = 1 \). If \( u \) is a non-terminal node, we set \( M_u[k-1] = 1 \) for all terminal nodes representing suffixes \( P[k..m-1] \) in the subtree rooted at \( u \), \( 0 < k < m - 1 \). This can be realised by using an Or bitwise operation between the bit vectors of the children of node \( u \). By applying this for all explicit nodes of \( ST_P \), we build \( \text{Occ-Vector}_P \). We have exactly \( m \) terminal nodes, and no more than \( m \) non-terminal nodes in \( ST_P \), thus, the bit vectors \( M_u \) for \( ST_P \) can be constructed in time \( O(m \cdot \lceil \frac{m}{\sigma} \rceil) \). The space required for \( \text{Occ-Vector}_P \) is \( O(m \cdot \lceil \frac{m}{\sigma} \rceil) \) since we have \( O(m) \) bit vectors and each bit vector requires space \( O(\lceil \frac{m}{\sigma} \rceil) \).

Theorem 13. Algorithm EDSM-BV solves the EDSM problem in an on-line manner in time \( O(N \cdot \lceil \frac{m}{\sigma} \rceil) \). Algorithm EDSM-BV requires preprocessing time and space \( O(m \cdot \lceil \frac{m}{\sigma} \rceil) \).

Proof. The correctness of the algorithm follows from the correctness of the KMP algorithm [13] if \( |S| \geq m, S \in T[i] \). By the definition of bit vectors \( I_c \), we read each \( S \in T[i] \), letter by letter, and try to extend the prefixes of \( P \), position by position, using Shift-And bitwise operations [17]. When we reach the end of the bit vector \( B_3 \), we may find an occurrence. No other occurrences can be found since we extend position by position, which means if we cannot reach the end of \( B_3 \), we must have had at least one mismatch which prevents the extension.

By Lemma 12, the time and space for the preprocessing of Algorithm EDSM-BV is bounded by \( O(m \cdot \lceil \frac{m}{\sigma} \rceil) \). For each \( S \in T[i], |S| \geq m \), searching \( P \) in \( S \) can be done in time \( O(|S|) \) using the KMP algorithm [13], which is bounded by \( O(N) \) for all \( S \). The Shift-And bitwise operation can be done in time \( O(|S| \cdot \lceil \frac{m}{\sigma} \rceil) \) [17], and it is repeated \( |S| \) or \( m - 1 \) times for each \( S \) to find an occurrence. Since we choose the minimum of \( |S| \) and \( m - 1 \), this time is bounded by \( O(|S| \cdot \lceil \frac{m}{\sigma} \rceil) \), which is bounded by \( O(N \cdot \lceil \frac{m}{\sigma} \rceil) \) for \( T \). By Lemma 7, sets \( B_{P,S} \) can be computed in time \( O(N) \). Updating \( B \) for position \( i = 0 \) and updating \( B_1 \) for each position \( i > 0 \) using sets \( B_{P,S} \) can be done in time \( O(N) \) for \( T \). For each \( S \in T[i], |S| < m \), \( \text{Occ-Vector}_P(S) \) requires time \( O(|S|) \) to return the corresponding bit vector, and updating \( B_1 \) requires time \( O(|S|) \) using bitwise operations. Note that \( B_1 \) needs only to be updated if \( B \neq 0 \). So for all \( T[i] \), the total time of this step can be bounded by \( O(N + N' \cdot \lceil \frac{m}{\sigma} \rceil) \), where \( N' \) is the number of strings \( S \) such that \( |S| < |P| \) and \( B \neq 0 \). Since \( N' \leq N \), this time is bounded by \( O(N \cdot \lceil \frac{m}{\sigma} \rceil) \).

The algorithm reads a position \( i \), and reports whether \( i \) is an ending position of some occurrence of \( P \), before reading position \( i + 1 \). Therefore, Algorithm EDSM-BV solves the EDSM problem in an on-line manner in time \( O(N \cdot \lceil \frac{m}{\sigma} \rceil) \), with preprocessing time and space \( O(m \cdot \lceil \frac{m}{\sigma} \rceil) \).
Experimental Results

We have implemented Algorithms EDSM and EDSM-BV in the C++ programming language. The implementation of the algorithm presented in [11], which we denote here by IKP, was taken from https://github.com/Ritu-Kundu/ElDeS. Recall that Algorithm IKP solves the EDSM problem in time $O(\alpha \gamma mn + N)$ and space $O(N)$; where $\alpha$ and $\gamma$ are parameters, respectively representing the maximum number of strings in any degenerate position of the text and the maximum number of degenerate positions spanned by any occurrence of the pattern in the text. Note that Algorithm IKP outputs both the starting and ending positions of pattern occurrences, while the output of Algorithms EDSM and EDSM-BV is only the ending positions. All three programs were compiled with g++ version 4.7.3 at optimisation level 3 (-O3). The following experiments were conducted on a desktop computer using one core of Intel® Core™ i7-2600S CPU at 2.8GHz and 8GB of RAM under 64-bit GNU/Linux. We compared the performance of EDSM, EDSM-BV, and IKP using synthetic data; as well as the performance of EDSM-BV—shown to be the fastest—using real data. The implementation of EDSM-BV is available at https://github.com/webmasterar/edsm under the terms of the GNU General Public License. The synthetic datasets referred to in this section are maintained at the same web-site.

**Synthetic data.** Synthetic ED texts were created randomly (uniform distribution over the DNA alphabet) with $n$ ranging from 100,000 to 1,600,000; and the percentage of degenerate positions was set to 10%. For each degenerate position within the synthetic ED texts, the number of strings was chosen randomly, with an upper bound set to 10. The length of each string of a degenerate position was chosen randomly, with an upper bound again set to 10. Every non-degenerate position within the synthetic ED texts contained a single letter. Four different patterns of length $m = 8, 16, 32$, or 64 were given as input to all three programs, along with the aforementioned synthetic ED texts, resulting in four sets of output.

Our theoretical findings showing that Algorithms EDSM and EDSM-BV are asymptotically faster than Algorithm IKP are validated in practice by the results illustrated in Figure 1. Note that the axes are in $\log_2$ scale. In particular, the results confirm that Algorithm EDSM-BV, which is asymptotically the fastest for short patterns, is also the fastest in practice by up to two orders of magnitude. As for Algorithm EDSM, not surprisingly, we observe that, as $m$ grows, the $m^2$ factor in its time complexity becomes more and more significant overall. Note that searching for much longer patterns exactly is not relevant in applications of interest, where errors (substitutions, insertions, and deletions) must be accommodated as $m$ grows.

**Real data.** EDSM-BV was tested further using real-world datasets. Human genomic data was obtained from the 1,000 Genomes Project [23]. Specifically, data was obtained from Phase 3 of the project, in which the genomes of 2,504 individuals from 26 different populations were sequenced and aligned, producing a dataset which summarises the variation in the sample population. Files in Variant Call Format (VCF) include information about variations at each position in the reference genome, which makes the format ideal for our purposes. EDSM-BV was given a reference sequence (in FASTA format) and variation data (in VCF) for each of the ten smallest chromosomes as input, as well as synthetic patterns of length $m = 8, 16, 32$, or 64. The average percentage of degenerate positions across these chromosomes was approximately 3%; the average number of strings at degenerate positions was 2; and the average length of strings at degenerate positions was 1. The processing time of EDSM-BV was recorded; with processing we refer only to the actual CPU time used in executing the process—excluding the
time to read the data in memory on-line. Chromosome 21, which is the smallest in length, has a VCF file of size 11.2GB. The results of this experiment are displayed in Figure 2.

The graphs in Figure 2 show, for the ten smallest chromosomes, a very clear linear relationship between the time taken for EDSM-BV to run and $N'$, the total number of strings $S \in T[i]$ such that $|S| < |P|$ and $B \neq 0$, per chromosome. Recall that the total time required by EDSM-BV for updating bit vector $B_1$ from $B$ is $O(N + N' \cdot \lceil \frac{m}{w} \rceil)$. This is the most time-consuming operation in practice as it searches for $S$ in the suffix tree of $P$ and then updates $B_1$ using bit-level operations. Note that, the total time to process strings $S \in T[i]$, with $|S| > |P|$, using KMP is $O(N)$, which becomes insignificant overall in practice.

7 Final Remarks

We have presented two efficient algorithms for on-line pattern matching on a set of similar texts. Notably, one of the algorithms requires time linear in the size of the texts’ representation, for short patterns, that is $O(N \cdot \lceil \frac{m}{w} \rceil)$. The presented experimental results confirm our theoretical findings in practical terms.

Our immediate target is to apply these on-line solutions for fast average-case approximate pattern matching or for multiple pattern matching on a set of similar texts. An open problem is to either improve on the $O(nm^2 + N)$-time algorithm or show conditional lower bounds.
On-Line Pattern Matching on Similar Texts

Abstract

In the Maximum Duo-Preservation String Mapping problem we are given two strings and wish to map the letters of the former to the letters of the latter as to maximise the number of duos. A duo is a pair of consecutive letters that is mapped to a pair of consecutive letters in the same order. This is complementary to the well-studied Minimum Common String Partition problem, where the goal is to partition the former string into blocks that can be permuted and concatenated to obtain the latter string.

Maximum Duo-Preservation String Mapping is APX-hard. After a series of improvements, Brubach [WABI 2016] showed a polynomial-time 3.25-approximation algorithm. Our main contribution is that, for any $\epsilon > 0$, there exists a polynomial-time $(2 + \epsilon)$-approximation algorithm. Similarly to a previous solution by Boria et al. [CPM 2016], our algorithm uses the local search technique. However, this is used only after a certain preliminary greedy procedure, which gives us more structure and makes a more general local search possible. We complement this with a specialised version of the algorithm that achieves 2.67-approximation in quadratic time.

1 Introduction

A fundamental question in computational biology and, consequently, stringology, is comparing similarity of two strings. A textbook approach is to compute the edit distance, that is, the smallest number of operations necessary to transform one string into another, where every operation is inserting, removing, or replacing a character. While this can be efficiently computed in quadratic time, a major drawback from the point of view of biological applications is that every operation changes only a single character. Therefore, it makes sense to also allow moving arbitrary substrings as a single operation to obtain edit distance with moves. Such relaxation makes computing the smallest number of operations NP-hard [17], but Cormode and Muthukrishnan [9] showed an almost linear-time $O(\log n \cdot \log^* n)$-approximation algorithm.

The problem is already interesting if the only allowed operation is moving a substring. This is usually called the Minimum Common String Partition (MCSP). Formally, we are given two strings $X$ and $Y$, where $Y$ is a permutation of $X$. The goal is to cut $X$ into the least number of pieces that can be rearranged (without reversing) and concatenated to obtain $Y$. © Bartłomiej Dudek, Paweł Gawrychowski, and Piotr Ostropolski-Nalewaja; licensed under Creative Commons License CC-BY
MCSP is known to be APX-hard [12]. Chrobak et al. [8] analysed performance of the simple greedy approximation algorithm, that in every step extracts the longest common substring from the input strings, and Kaplan and Shafrir [16] further improved their bounds. This simple greedy algorithm can be implemented in linear time [13], and further tweaked to obtain better practical results [14]. Also, an exact exponential time algorithm [11] and different parameterizations were considered [15, 5, 6, 10].

There was also some interest in the complementary problem called the Maximum Duo-Preservation String Mapping (MPSM), introduced by Chen et al. [7]. The goal there is to map the letters of \( X \) to the letters of \( Y \) as to maximise the number of preserved duos. A duo is a pair of consecutive letters, and a duo of \( X \) is said to be preserved if its pair of consecutive letters is mapped to a pair of consecutive letters of \( Y \) (in the same order). MCSP and MPSM are indeed complementary, as one can think of preserving a duo as not splitting its two letters apart to see that the number of preserved duos and the number of pieces add up to \(|X|\). Of course, this does not say anything about the relationship between the approximation guarantees for both problems. Chen et al. [7] designed a \( k^2 \)-approximation algorithm based on linear programming for the restricted version of the problem, called \( k \)-MPSM, where each letter occurs at most \( k \) times. This was soon followed by an APX-hardness proof of 2-MPSM and a general 4-approximation algorithm provided by Boria et al. [3]. The approximation ratio was then improved to 3.5 [2] using a particularly clean argument based on local search. Finally, Brubach [4] obtained a 3.25-approximation, and Beretta et al. [1] considered parameterized tractability.

Our main contribution is a family of polynomial-time approximation algorithms for MPSM: for any \( \varepsilon > 0 \), we show a polynomial-time \((2 + \varepsilon)\)-approximation algorithm. We complement this with a specialised (and simplified) version of the algorithm that achieves 2.67-approximation in quadratic time, which already improves on the approximation guarantee and the running time of the previous solutions, as the running time of the 3.5-approximation was \( O(n^4) \). At a high level, we also apply local search, that is, we iteratively try to slightly change the current solution as long as such a change leads to an improvement. The intuition is that not being able to find such local improvement should imply a \((2 + \varepsilon)\)-approximation guarantee. This requires considering larger and larger neighbourhoods of the current solution for smaller and smaller \( \varepsilon \) and seems problematic already for \( \varepsilon = 1 \). To overcome this, we apply local search only after a certain preliminary greedy procedure, which gives us more structure and makes a more general local search possible.

## 2 Preliminaries

In the Maximum Duo-Preservation String Mapping (MPSM) we are given two strings \( X \) and \( Y \), where \( Y \) is a permutation of \( X \). The goal is to map the letters of \( X \) to the letters of \( Y \) as to maximise the number of preserved duos. A duo is a pair of consecutive letters, and a duo of \( X \) is said to be preserved if its pair of consecutive letters is mapped to a pair of consecutive letters of \( Y \) (in the same order). This can be restated by creating a bipartite graph \( G = (A \cup B, E) \), where \( n = |X| - 1 = |A| = |B| \) and \( A = \{a_1, a_2, \ldots, a_n\} \) and \( B = \{b_1, b_2, \ldots, b_n\} \). Node \( a_i \) corresponds to duo \((X[i], X[i+1])\) and similarly \( b_i \) corresponds to \((Y[i], Y[i+1])\). Two nodes are connected with an edge if their corresponding duos are the same, that is, \( E = \{(a_i, b_j) : X[i] = Y[j] \text{ and } X[i+1] = Y[j+1]\} \). See Figure 1.

Now, we want to find a maximum matching in \( G \) that corresponds to a proper mapping of letters between the strings, that is, such that every two consecutive mapped duos (consisting of three consecutive letters) are mapped to two consecutive duos (in the same order). It is
not necessary that all duos are mapped. Formally, a matching $M$ is called consecutive if every two neighbouring nodes are either matched to two neighbouring nodes (preserving the order) or at least one of them is unmatched:

$$\forall i,j,j' \in \{1..n\} ((a_i, b_j) \in M \land (a_{i+1}, b_{j'}) \in M) \Rightarrow (j' = j + 1)$$

and a symmetric condition for the other side of the graph. Even though the graph $G$ obtained as described above from an instance of MPSM has some additional structure, we focus only on the more general problem where the given bipartite graph $G = (A \cup B, E)$ is arbitrary and we are looking for a consecutive matching of maximum cardinality. This was called the Maximum Consecutive Bipartite Matching (MCBM) by Boria et al. [3].

**Definitions.** We say that two edges $(a_i, b_j)$ and $(a_{i'}, b_{j'})$ are overlapping if $|i - i'| \leq 1$ or $|j - j'| \leq 1$. Given a consecutive matching $M$, we define a streak to be a maximal (under inclusion) set of consecutive edges $e_1, e_2, \ldots, e_k$, such that for some $p, q$ we have that $e_i = (a_{p+i}, b_{q+i})$ for all $i = 1, 2, \ldots, k$. See Figure 2. Note that from the definition, $e_i$ overlaps with itself, $e_{i-1}$ and $e_{i+1}$ (assuming that these edges exist). This notion is extended to sets of edges: $S_1$ overlaps with $S_2$ if there exist $e_1 \in S_1, e_2 \in S_2$ such that $e_1$ overlaps with $e_2$. Similarly, we define overlaps between an edge and a set of edges. Note that every consecutive matching $M$ can be uniquely decomposed into a set of streaks such that no two of them are overlapping with each other.

### 3 Greedy Algorithm

Consider a simple greedy procedure, that in every step takes the longest possible streak from $G$ and, if the streak consists of at least $k$ edges, adds it to the solution. See Algorithm 1.

To analyse quality of the returned solution, we fix an optimal solution $OPT$ and would like to compare $|ALG|$ with $|OPT|$. Let $s_i$ be the streak that was removed in the $i$-th step of the algorithm and $o_i$ be the set of edges from $OPT$ that are overlapping with $s_i$, but were not overlapping with $s_1, s_2, \ldots, s_{i-1}$. In other words, $o_i$ consists of those edges from $OPT$ that after $i - 1$ steps of the algorithm still could have been added to the solution, but are no longer available after the $i$-th step. Note that $o_i$ contains all the edges of $OPT \cap s_i$, because every edge overlaps with itself. Observe that $|o_i| \leq 2|s_i| + 4$ as there can be at most $|s_i| + 2$ edges from $o_i$ overlapping with $s_i$ at each side of $G$. Moreover, even a stronger property holds:
Algorithm 1 Choosing the largest possible streak greedily.

1: function Greedy($k$)
2: \( ALG := \emptyset \)
3: \( \) 
4: \( s := \) the largest streak in \( G \)
5: \( \) 
6: \( \) if \( |s| < k \) then
7: \( \) break
8: \( ALG := ALG \cup s \)
9: \( \) return \( ALG \)

\[ \textbf{Lemma 1.} \ |o_i| \leq 2|s_i| + 2. \]

\textbf{Proof.} Suppose that the endpoints of \( s_i \) at one side of the graph (say \( A \)) form a sequence of nodes \( a_j, a_{j+1}, \ldots, a_{j+|s_i|-1} \). Define \( \mathcal{E} = \{a_{j-1}, a_j, \ldots, a_{j+|s_i|-1}, a_{j+|s_i|}\} \) (assuming that \( a_{j-1} \) and \( a_{j+|s_i|} \) exist). We will show that at most \( |s_i| + 1 \) edges from \( o_i \) can end in \( \mathcal{E} \). Then, applying the same reasoning to the other side of the graph will finish the proof. If \( |\mathcal{E}| < |s_i| + 2 \) then the claim holds. Otherwise, if \( |\mathcal{E}| = |s_i| + 2 \) there are three cases to consider:

1. There are two or more streaks from \( o_i \) ending in \( \mathcal{E} \). Then they cannot end in all nodes from \( \mathcal{E} \), because at least two of them would be overlapping with each other. Thus there is at least one node from \( \mathcal{E} \) that is not an endpoint of edge from \( o_i \), so there are at most \( |s_i| + 1 \) of them.
2. There is one streak from \( o_i \) ending in \( \mathcal{E} \). Then the streak cannot be larger than \( |s_i| \), because then the greedy algorithm would have taken the larger streak (recall that \( o_i \) consists of edges that could have been added to the solution in the \( i \)-th step). Thus there are at most \( |s_i| \) edges of \( o_i \) ending in \( \mathcal{E} \).
3. There is no streak from \( o_i \) ending in \( \mathcal{E} \). Then the statement holds trivially.

We still need to specify the algorithm for smaller streaks (consisting of less than \( k \) edges), but before doing so in the next section we bound the quality of the solution found by the greedy algorithm.

Let \( m \) be the number of steps performed by the greedy algorithm. The algorithm returns \( ALG = \bigcup_{i=1}^{m} s_i \) which should be compared with the set of edges of \( OPT \) that can no longer be taken due to the decisions made by the greedy algorithm, that is, \( \bigcup_{i=1}^{m} o_i \subseteq OPT \). Using Lemma 1 we can compute the desired ratio as follows:

\[ \frac{|\bigcup_{i=1}^{m} o_i|}{|\bigcup_{i=1}^{m} s_i|} \leq \frac{\sum_{i=1}^{m} |o_i|}{\sum_{i=1}^{m} |s_i|} \leq \frac{\sum_{i=1}^{m} (2|s_i| + 2)}{\sum_{i=1}^{m} |s_i|} = 2 + \frac{m \cdot 2}{\sum_{i=1}^{m} |s_i|} \leq 2 + \frac{m \cdot 2}{m \cdot k} = 2 + \frac{2}{k} \]

where the last inequality holds because all taken streaks consist of at least \( k \) edges.

To conclude, the solution \( ALG \) found by the greedy algorithm is at most \( 2 + \frac{2}{k} \) times smaller than the set of edges from \( OPT \) that is overlapping with \( ALG \). Informally, on average we discard only a few edges of \( OPT \) for every edge from \( ALG \). After running the algorithm for \( k = 1 \), there will be no edges left and thus we have a simple 4-approximation algorithm. To obtain a better approximation ratio, we will increase \( k \) and focus on the subgraph \( G' \) of \( G \) consisting of all edges that are not overlapping with any streak \( s_i \) already taken by the algorithm (and hence still available). The crucial insight is that we can analyse the performance of the greedy algorithm on \( G \setminus G' \) and the performance of the algorithm for small \( k \) on \( G' \) separately. We know that the approximation ratio of the greedy algorithm on
For every edge of\( 3.\)
\(4.\) Let\( 2.\)
Find the maximum matching\( 1.\)
Return\( 5.\)

As stated above, applying the greedy algorithm with\( k \) we need another phase to find a solution for the remaining part of the graph. For \( k = 2 \), we present a simple algorithm based on maximum bipartite matching (not consecutive) that can be used to obtain a 3-approximation. For larger values of \( k \), we first consider \( k = 3 \) and design a quadratic-time algorithm based on the local search technique. Then, we move to a general \( k \) and develop a more involved polynomial-time algorithm that achieves \((2 + \varepsilon)\)-approximation.

### 3-approximation Based on Maximum Matching for \( k = 2 \)

After running Greedy(2) there are no streaks of size 2. Recall that \( G' = (A \cup B, E') \) is the subgraph of the original graph \( G \) consisting of all edges that are not overlapping with the already taken edges. Consider the following algorithm:

1. Create a bipartite graph \( H = (A' \cup B', F) \) where:
   - \( A' = \{a_{(1,2)}, a_{(3,4)}, \ldots, a_{(n-1,n)}\} \) and similarly for \( B' \). In other words, nodes of \( A' \) correspond to merged pairs of neighbouring nodes of \( A \) (if \( n \) is odd, the last node of \( A' \) corresponds to a single node of \( A \)).
   - \( F = \{\{a_{(2i-1,2i)}, b_{(2j-1,2j)}\} : a_{2i-1} = a_{2i} \times (b_{2j-1}, b_{2j}) \cap E' \neq \emptyset\}. \) In other words, there is an edge between two merged pairs of nodes if there was an edge between a node from the first pair and a node from the second pair.
2. Find the maximum matching \( M' \) in \( H \).
3. For every edge of \( M' \), choose an edge of \( G' \) connecting nodes from the corresponding pairs (if there are multiple possibilities, choose any of them). Let \( M \) be the set of chosen edges.
4. Let \( ALG \leftarrow \emptyset \). Process all edges of \( M \) in arbitrary order. For an edge \((a_i, b_j) \in M: \)
   - remove from \( M \) all edges ending in nodes \( a_{i-1}, a_{i+1}, b_{j-1} \) and \( b_{j+1} \),
   - add \((a_i, b_j)\) to \( ALG \).
5. Return \( ALG \).

Consider the optimal solution \( OPT \). As \( G' \) contains no streaks consisting of 2 or more edges, the endpoints of any two of its edges cannot be neighbouring. Therefore, \( OPT \) can be translated into a matching in \( H \) with the same cardinality, so \(|OPT| \leq |M'|\).

We claim that after including an edge \((a_i, b_j) \in M \) in \( ALG \) at most 2 other edges are removed from \( M \). Assume otherwise, that is, there are 3 such edges. Without loss of generality, one of them ends in \( a_{i-1} \) and one in \( a_{i+1} \). Depending on the parity of \( i \), edge \((a_i, b_j)\) and the edge ending in either \( a_{i-1} \) or \( a_{i+1} \) correspond in \( H \) to edges ending in the same node of \( A' \). This is a contradiction, because all edges in \( M' \) have distinct endpoints. Because initially \(|M'| = |M|\), we conclude that \(|ALG| \geq |M'|/3\).

Combining the inequalities gives us \( 3 \cdot |ALG| \geq |M'| \geq |OPT| \), so the above algorithm is a 3-approximation for graphs with no streaks of size at least 2. Combining it with Greedy(2), that guarantees approximation ratio of \( 2 + 2/k \), gives us a 3-approximation algorithm for the whole problem.

3: while true do
4:   if $\exists e \notin ALG$ s.t. $ALG \cup \{e\}$ is a valid solution then
5:     $ALG := ALG \cup \{e\}$
6:   if $\exists e_1, e_2 \notin ALG, e' \in ALG$ s.t. $ALG \setminus \{e'\} \cup \{e_1, e_2\}$ is a valid solution then
7:     $ALG := ALG \setminus \{e'\} \cup \{e_1, e_2\}$
8:   if $|ALG|$ was not increased then
9:     break
10: return $ALG$

4.2 2.67-approximation for $k = 3$

For $k = 3$ we use procedure LOCALIMPROVEMENTS based on the local search technique. See Algorithm 2. Essentially the same method was used to obtain the 3.5-approximation [2]. The algorithm consists of a number of steps in which it tries to either add a single edge or remove one edge so that two other edges can be added. However, the crucial difference is that in our case there are no streaks of size greater than 2 in $G'$. This allows for a better bound on the approximation ratio.

Fix an optimal solution $OPT$. We want to bound the total number $C$ of overlaps between the edges from $ALG$ and $OPT$. First, observe that an edge from $ALG$ can overlap with at most 4 edges from $OPT$, because there are no streaks of size 3 in the graph. Thus:

$$4 \cdot |ALG| \geq C.$$  \hfill (1)

Second, let $k_1$ be the number of edges from $OPT$ that overlap with exactly one edge from $ALG$. Then all other edges from $OPT$ overlap with at least two edges from $ALG$ (because otherwise the algorithm would have taken an edge not overlapping with any already taken edge), so:

$$C \geq k_1 + 2 \cdot (|OPT| - k_1) = 2 \cdot |OPT| - k_1.$$  \hfill (2)

Lemma 2. $k_1 \leq |ALG|$.

Proof. Suppose that $k_1 > |ALG|$. Then there are two edges $e_1, e_2 \in OPT$ that overlap with only one and the very same edge $e_{del} \in ALG$. But then the algorithm would have increased size of the solution by removing $e_{del}$ and adding $e_1$ and $e_2$, so we obtain a contradiction. \hfill $\blacktriangle$

Applying Lemma 2 to (2) and combining with (1) we get $4 \cdot |ALG| \geq C \geq 2 \cdot |OPT| - |ALG|$ and thus $2.5 \cdot |ALG| \geq |OPT|$. Recall that the approximation ratio of the first greedy part of the algorithm is $2 + \frac{2}{3} < 2.67$, so the overall ratio of the combined algorithm is also 2.67. The algorithm clearly runs in polynomial time as in every iteration of the main loop the size of $ALG$ increases by one and is bounded by $n$. In [2] the running time was further optimised to $O(n^4)$, but in the remaining part of this section we will describe how to decrease the time to $O(n^2)$. We will also show how to implement the greedy algorithm in the same $O(n^2)$ complexity, thus obtaining an 2.67-approximation algorithm in $O(n^2)$ time.

Greedy part in $O(n^2)$ time. We show how to implement GREEDY($k$) in $O(n^2)$ time. Recall that in every iteration the algorithm chooses the longest streak in the remaining part of the
The procedure terminates if the streak contains less than two smaller streaks. In both cases, the smaller streak(s) is moved between the appropriate

Having split all edges into streaks and grouped streaks by their sizes, we iterate over the groups $D_n, D_{n-1}, \ldots, D_k$ and retrieve a streak $s$ from the non-empty group with the largest index. We add $s$ to the solution and remove all edges overlapping with $s$ from the graph. Every removed edge either decreases the size of its streak by one or splits it into two smaller streaks. In both cases, the smaller streak(s) is moved between the appropriate groups. Removing an edge takes constant time and every edge is removed at most once from the graph. Similarly, moving or splitting of a streak due to a removed edge takes constant time as the size of the smaller streak can be computed in constant time by looking at its first and last edge. Thus, the overall time of the procedure is $O(n^2)$.

**Remark.** Recall that we have generalised the MPSM problem and now are working with an arbitrary bipartite graph $G$. However, if $G$ was constructed from an instance of MPSM, then finding the longest available streak corresponds to finding the longest string that occurs in both $X$ and $Y$ without overlapping with any of the previously chosen substrings. Goldstein and Lewenstein [13] showed how to implement such a procedure in $O(n)$ total time.

**Local improvements in $O(n^2)$ time.** Recall that to analyse the approximation ratio (in Lemma 2), we only need that after termination of the algorithm there are no three edges $e_1, e_2 \notin ALG, e_{del} \in ALG$ such that $ALG \setminus \{e_{del}\} \cup \{e_1, e_2\}$ is a valid solution. At a high level, FastLocalImprovements keeps track of edges that can potentially increase size of the solution in a queue $Q$. As long as $Q$ is not empty, we retrieve a candidate edge $e$ from $Q$. First, we verify that $e \notin ALG$ and $e$ overlaps with at most one edge from $ALG$. If $e$ can be added to $ALG$, we do so and continue after adding to $Q$ all edges overlapping with $e$. Otherwise, we check if some other edge $e'$ can be added while removing another edge $e_{del}$ at the same time using procedure TryAddingPairWith$(e)$, and if so, we add to $Q$ all edges overlapping with one of the modified edges ($e, e'$ and $e_{del}$). See Algorithm 3 and Algorithm 4.

The algorithm uses the following data structures and functions:

- For every node $v \in G'$, we keep a list of all edges from $E$ ending in $v$ and separately edges of $ALG$ ending in $v$.
- $Close(e)$ is the set of nodes of $G'$ at distance at most 1 from the endpoints of edge $e$. In other words, $Close(e)$ is the set of up to 6 nodes where edges overlapping with $e$ can end.
- $Overlap(e)$ is the set of edges overlapping with edge $e$. It is computed on the fly, by iterating through edges ending in $v \in Close(e)$.
- Queue $Q$ of candidate edges. For every edge in $E$ we remember if it is currently in $Q$ in order not to store any duplicates and keep the space usage $O(m)$.
- For every node $v \in G'$ we keep a list $L_v$ of edges from $E \setminus ALG$ that overlap with exactly one edge from $ALG$ and end in $v$. To keep these lists updated, every time an edge $e = \langle x, y \rangle$ is enqueued or added or removed from $ALG$, we count the edges from $ALG$ it

7:         return
8:     for each node $v \in \text{Close}(e_{\text{del}}) \setminus \text{Close}(e)$ do \Comment{$O(1)$ see Lemma 3}
9:         for each edge $e' \in L_v$ do
10:             if $ALG \setminus \{e_{\text{del}}\} \cup \{e, e'\}$ is a valid solution then
11:                $ALG := ALG \setminus \{e_{\text{del}}\} \cup \{e, e'\}$
12:                $Q = \text{ENQUEUE}(\text{Overlap}(e) \cup \text{Overlap}(e') \cup \text{Overlap}(e_{\text{del}}))$
13:         return

overlaps with. If there is only one of them, we make sure that $e$ is in $L_x$ and $L_y$, otherwise we remove $e$ from $L_x$ and $L_y$.

Clearly, after termination of the algorithm there is no triple of edges $e_1, e_2$ and $e_{\text{del}}$ that can be used to increase the solution, because every time an edge is added to or removed from the solution, all of its overlapping edges are enqueued. It remains to prove that Algorithm 3 indeed runs in $O(n^2)$ time. First, observe that $|\text{Close}(e)| \leq 6$, so from the definition of overlapping edges $|\text{Overlap}(e)| \leq |\text{Close}(e)| \cdot n \in O(n)$, as there are at most $n$ edges ending in a node. So, every time the algorithm enqueues a set of edges, there are at most $O(n)$ of them. As this happens only after increasing the size of $ALG$, which can happen at most $n$ times, in total there are $O(n^2)$ enqueued edges. So it suffices to prove that every time an edge $e$ is dequeued, it takes $O(1)$ time to check if it can be used to increase the solution. Here we disregard the time for enqueuing edges due to increasing the size of $ALG$, as it adds up to $O(n^2)$ as mentioned before. Note that both counting the edges overlapping with $e$ and finding the unique edge from $ALG$ overlapping with $e$ takes $O(1)$ time, as we just need to check edges from $ALG$ ending in $\text{Close}(e)$. Similarly, as $ALG$ is always a valid solution, each validity check takes $O(1)$ time, as we always try to modify a constant number of edges. By the same argument, loops in lines 3 and 8 take constant number of iterations, and also:

- **Lemma 3.** There are $O(1)$ iterations of the loop in line 9 of TryAddingPairWith($e$).
Algorithm 5 Improvements of bounded size.

1: function BOUNDEDSIZEIMPROVEMENTS($t$)
2: $ALG := \emptyset$
3: while true do
4:     for each $E_{\text{remove}}, E_{\text{add}} \subseteq E$ such that $|E_{\text{remove}}| < |E_{\text{add}}| \leq t$ do
5:         $ALG' := ALG \setminus E_{\text{remove}} \cup E_{\text{add}}$
6:         if $ALG'$ is a valid solution then
7:             $ALG := ALG'$
8:             break
9:     if $ALG$ was not improved then
10:        break
11: return $ALG$

Proof. Consider an edge $e' \in L_v$ such that $ALG' := ALG \setminus \{e_{\text{del}}\} \cup \{e, e'\}$ is not a valid solution. From the definition of $L_v$, $e'$ overlaps only with $e_{\text{del}} \in ALG$, so both $ALG \setminus \{e_{\text{del}}\} \cup \{e\}$ and $ALG \setminus \{e_{\text{del}}\} \cup \{e'\}$ are valid solutions. Thus, the only reason for $ALG'$ not being valid is that $e'$ overlaps with $e$. But $v$ is at distance 2 or more from the endpoint of $e$, so $e$ and $e'$ can be overlapping only at the other side of the graph. There are at most 3 possible endpoints of such $e'$ at the other side, see Figure 3. Consequently, after checking 4 edges from $L_v$ we will surely find one that can be used to increase $|ALG|$.

To conclude, GREEDY(3) with FASTLOCALIMPROVEMENTS yield 2.67-approximation in $O(n^2)$ time.

5 (2 + $\varepsilon$)-approximation

Given $\varepsilon > 0$ we would like to create a polynomial time $(2 + \varepsilon)$-approximation algorithm. We set $k = \lceil \frac{1}{\varepsilon} \rceil$ and run GREEDY($k$) to remove all streaks of size at least $k$ from the graph $G$. From now we focus on the subgraph $G'$ remaining after the first greedy phase and let $OPT$ denote the optimal solution in $G'$.

Let $t = \lceil \frac{k}{2} \rceil + 1$ and $ALG$ be the solution found by BOUNDEDSIZEIMPROVEMENTS($t$), see Algorithm 5. Similarly to the case $k = 3$, the algorithm tries to improve the current solution using local optimisations, however now the number of edges that we try to add or remove in every step is bounded by $t$ (that depends on $\varepsilon$). We want to prove that $(2 + \varepsilon) \cdot |ALG| \geq |OPT|$. To this end, we assign $(2 + \varepsilon)$ units of credit to every edge of $ALG$. Then the goal is to distribute the credits from the edges of $ALG$ to the edges of $OPT$, so that every edge of $OPT$ receives at least one credit. Alternatively, we can think of transferring credits to the streaks from $OPT$, in such a way that a streak consisting of $s$ edges receives at least $s$ credits. This will clearly demonstrate the required inequality.
Credit distribution scheme. Every edge from \( ALG \) distributes \((1 + \frac{\epsilon}{2})\) credits from each of its two endpoints independently. Consider an endpoint \( v_i \) of an edge from \( ALG \). Let \( \ldots, v_{i-1}, v_i, v_{i+1}, \ldots \) be all nodes at the corresponding side of the graph \( G \). If there is an edge \( e \in OPT \) ending in \( v_i \), then \( e \) receives 1 credit. Now consider the case when no edge of \( OPT \) ends in \( v_i \). If exactly one edge from \( OPT \) ends in \( v_{i+1} \) or \( v_{i-1} \) then the credit is transferred to that edge. If there are no edges ending there then the credit is not transferred at all. Finally, if there is an edge \( e \in OPT \) ending at \( v_{i-1} \) and another edge \( e' \in OPT \) ending at \( v_{i+1} \), then for the time being neither \( e \) nor \( e' \) receives the credit. In such a situation we say that the node \( v_i \) is between the streak containing \( e \) and the streak containing \( e' \), call the credit uncertain and defer deciding whether it should be transferred to \( e \) or \( e' \). Observe that the only case when an edge \( e \in ALG \) overlapping with a streak \( s \) does not transfer the credit to \( s \) is when the endpoint of \( e \) is between two streaks \( s \) and \( s' \), see Figure 4. Note that two credits can be transferred from \( e \) to \( s \) if both endpoints of \( e \) transfer its credits to \( s \). The remaining \( \frac{\epsilon}{2} \) credits are not transferred to any specific edge yet. We will aggregate and redistribute them using a more global argument, but first need some definitions.

Gaps and balance. Define the balance of a streak \( s \) from \( OPT \) as the number of credits obtained in the described scheme (ignoring the uncertain credits) minus the number of edges in \( s \). A gap is an edge of \( OPT \) that has not received any credits yet and \( \text{gaps}(s) \) is the number of gaps in \( s \). Observe that the balance of a streak \( s \) is at least \(-\text{gaps}(s)\). After running the greedy algorithm and \text{BoundedSizeImprovements}(t), even a stronger property holds:

\[ \text{Lemma 4. The balance of every streak is at least } -2. \]

\[ \text{Proof. Consider a streak } s. \text{ If there are less than 2 gaps in } s \text{ then the claim holds. Otherwise, let } g_1 \text{ and } g_2 \text{ be the first and the last gap in } s, \text{ so that we can write } s = Ag_1Mg_2B, \text{ see Figure 5. Note that the balance of both } A \text{ and } B \text{ is non-negative, as from the definition there are no gaps inside, so every edge there receives at least one credit. However, there might be multiple gaps in } M. \text{ Suppose that the balance of } M \text{ is negative. But the size of } M \text{ is smaller than } k < t, \text{ so } \text{BoundedSizeImprovements}(t) \text{ would have replaced a subset of edges from } ALG \text{ with } M \text{ to increase size of the solution. Therefore, the balance of } M \text{ is nonnegative. Finally, observe that the balance of } s \text{ is equal to the sum of balances of } A, M \text{ and } B \text{ minus 2 (for the gaps } g_1 \text{ and } g_2), \text{ so it is at least } -2 \text{ in total.} \]

The following corollary that follows from the above proof will be useful later:

\[ \text{Corollary 5. Every streak } s \text{ with balance } -2 \text{ can be represented as } s = Ag_1Mg_2B \text{ where } g_1 \text{ and } g_2 \text{ are the first and last gap of } s, \text{ respectively. The balance of } Ag_1 \text{ and } g_2B \text{ is } -1 \text{ while the balance of } M \text{ is 0.} \]

Analysis of the scheme. We construct an auxiliary multi-graph \( H \), where the vertices are streaks of \( OPT \) with balance at least \(-1\). Streaks with balance \(-2\) are split into two smaller
streaks (called substreaks) with balance $-1$ as explained in Corollary 5. We create an edge between two streaks in $H$ when they both overlap with an endpoint of an edge from $ALG$. In other words, when edge $e$ from $ALG$ has an endpoint $x$ overlapping with two streaks of $OPT$, then there is an edge in $H$ between the vertices corresponding to these streaks, see Figure 6. Observe that then there is no edge of $OPT$ ending in $x$ and there can be at most two edges between any pair of streaks.

Now we will show that for every connected component of $H$ there are enough credits to distribute at least one credit to every edge from $OPT$ in the component. The intuition behind considering the connected components of $H$ is that we have deferred distribution of the uncertain credits, and now a connected component is a set of streaks that needs to decide together how to spend those uncertain credits. At a high level, for every connected component $C$ of $H$ there will be two cases to consider. First, if the balance of $C$ is non-negative, then we are done. Otherwise, we will show that the balance of $C$ is equal to $-1$. We also know that the component is so big that $\text{BoundedSizeImprovements}$ was not able to increase the solution. From this we will conclude that, by gathering the remaining $\frac{\varepsilon}{2}$ credits together, it is possible to cover the deficit.

Consider one connected component $C$ on $w$ vertices. We want to prove that there are at least $w$ credits transferred to all edges of $C$ in total. From the construction we have that every vertex of $C$ has balance at least $-1$. Moreover, as the component is connected, there are at least $w - 1$ edges, each adding one uncertain credit. Thus, the total balance of the whole component (including the uncertain credits) is at least $-1$. Observe that the only case when the total balance of the component is $-1$ is a tree (with exactly $w - 1$ edges) where every node has balance $-1$. In all other cases the balance is non-negative already.

We denote by $K_C$ the set of edges of $OPT$ from all vertices of $C$ (recall that they correspond to original streaks with balance $-1$ and substreaks). We also define an auxiliary set $M_C$ that consists of the middle parts $M$ of the original streaks. More precisely, for every streak $s$ of balance $-2$, if it was a part of $C$ (due to the substreak $Ag_1$ or $g_2B$, where $s = Ag_1Mg_2B$), we add to $M_C$ all edges from $M$. From Corollary 5, the balance of every such $M$ is 0. Now consider the following set of edges $X_C = K_C \cup M_C$. There are two cases to consider depending on how many credits have been transferred to $X_C$:

1. If there are at least $c \geq \frac{2}{3}$ credits transferred to the edges of $X_C$ (each credit from an endpoint of an edge from $ALG$), then we can use half of the remaining $\frac{\varepsilon}{2}$ credit of each
endpoints and transfer it to the component. Note that for each credit from those $c$ already assigned to $X_C$ there is one endpoint still having additional $\frac{\varepsilon}{2}$ credit that can be spent on $X_C$. We can use only half of the remaining $\frac{\varepsilon}{2}$ credit because some edges (from the middle parts of original streaks) can belong to both $X_C$ and $X_{C'}$ for two different components $C$ and $C'$, see Figure 7, and they might need to transfer additional credit to both of them. Thus, for each of the $c$ credits we transfer additional $\frac{\varepsilon}{4}$ credit, so in total we transfer at least one full credit, which is enough to cover the deficit of the component.

2. In the second case, the edges from $X_C$ received less than $\frac{1}{2} + \varepsilon$ credits, so there are less than $\frac{1}{2} + 1$ edges from $OPT$ (recall that the overall balance of the component is $-1$). Note that if we add all edges from $X_C$ and remove all edges from $ALG$ that have transferred credits to the edges from $X_C$, the size of the solution will increase as earlier the overall balance was negative. The solution will still be valid, because we have removed all edges from $ALG$ overlapping with the edges of $X_C$. Also for the split streaks, we took edges up to (but not including) a gap which from the definition does not share an endpoint with an edge from $ALG$. Furthermore, as the size of $X_C$ is at most $\frac{1}{2} + 1 \leq t$, it would have been considered as the set $E_{add}$ of edges to be checked by our algorithm. Thus, this case is impossible, as we would have been able to improve the current solution.

To conclude, every connected component containing $w$ edges receives at least $w$ credits, so $(2 + \varepsilon) \cdot |ALG| \geq |OPT|$. As the approximation ratio of the first greedy part is also $(2 + \varepsilon)$, as explained before the overall algorithm is an $(2 + \varepsilon)$-approximation for MPSM. It remains to analyse its time complexity. Let $m$ denote the number of edges of $C'$. There are at most $n$ steps of the algorithm, as in each of them size of the solution increases by at least one and is bounded by $n$. There are $\binom{n}{t+1} \in O(m^t)$ candidates for $E_{add}$ and $E_{remove}$ and we can check in $O(m)$ time if a given solution is valid. In total, substituting $t = \left\lfloor \frac{1}{2} \right\rfloor + 1$ the total time complexity is $O(m^{2t+1}) = O(n^{4t+2}) = O(n^{16+6\varepsilon}) = O(n^{O(1/\varepsilon)})$.

▶ Theorem 6. Combining the greedy algorithm with local improvements yields a $(2 + \varepsilon)$-approximation for MCBM in $n^{O(1/\varepsilon)}$ time, for any $\varepsilon > 0$.

▶ Corollary 7. There exists a $(2 + \varepsilon)$-approximation algorithm for MPSM running in $n^{O(1/\varepsilon)}$ time, for any $\varepsilon > 0$.

Abstract
In the Maximum-Duo Preservation String Mapping (Max-Duo PSM) problem, the input consists of two related strings A and B of length n and a nonnegative integer k. The objective is to determine whether there exists a mapping m from the set of positions of A to the set of positions of B that maps only to positions with the same character and preserves at least k duos, which are pairs of adjacent positions. We develop a randomized algorithm that solves Max-Duo PSM in time $4^k \cdot n^{O(1)}$, and a deterministic algorithm that solves this problem in time $6.855^k \cdot n^{O(1)}$. The previous best known (deterministic) algorithm for this problem has running time $(8e)^{2k+o(k)} \cdot n^{O(1)}$ [Beretta et al., Theor. Comput. Sci. 2016]. We also show that Max-Duo PSM admits a problem kernel of size $O(k^3)$, improving upon the previous best known problem kernel of size $O(k^6)$.

1 Introduction

Computing distances between strings is a fundamental task in computer science. For many distance measures, the distance between two strings A and B is defined as the minimum number of local operations that are needed to transform A into B, for example the deletion or insertion of a character. For these measures, the distance between two strings A and B can be usually computed in polynomial time [13, 22]. In some applications, however, it is necessary to consider nonlocal operations that transform one string into the other. In comparative genomics, for example, genomes are modeled as strings with one character corresponding to a complete gene and one is interested in determining the evolutionary distance between two genomes. During biological evolution, genomes may be altered by large-scale mutations such as the reversal or the transposition of larger parts of the genome [19].

One approach to approximate the distance between two strings A and B with respect to many of these operations is to compute a smallest common string partition [11, 26].

* Christian Komusiewicz gratefully acknowledges support from the DFG, project MAGZ (KO 3669/4-1).
Mateus de Oliveira Oliveira gratefully acknowledges support from the Bergen Research Foundation.
Informally, a size-\(\ell\) common string partition of two strings \(A\) and \(B\) is a partition of \(A\) and \(B\), each into \(\ell\) nonoverlapping substrings, such that the resulting two multisets of substrings of \(A\) and \(B\) are the same. The problem to compute a smallest common string partition, known as \textsc{Minimum Common String Partition}, is \textsc{NP}-hard [11, 21].

An alternative way of defining such a partition is to ask for a partition of \(A\) into \(\ell\) nonoverlapping substrings such that permuting the order of these substrings and concatenating them subsequently gives the string \(B\). This second view implies a mapping \(m\) that (bijectively) maps each position \(i\) of \(A\) to a position \(m(i)\) of \(B\) such that \(A[i] = B[m(i)]\). The size of the common string partition is then exactly the number of pairs of consecutive positions \(i\) and \(i+1\) such that \(m(i)+1 \neq m(i+1)\); these positions are called duos. Therefore, computing a mapping \(m\) that maps only positions with the same characters to each other and maximizes the number \(k\) of consecutive positions for which \(m(i)+1 = m(i+1)\) directly yields a minimum common string partition of \(A\) and \(B\). The problem of computing such a mapping is known as \textsc{Maximum-Duo Preservation String Mapping} (\textsc{Max-Duo PSM}). Since \textsc{Max-Duo PSM} is simply a dual of the \textsc{Minimum Common String Partition} problem, it is \textsc{NP}-hard as well. Motivated by this hardness, we study \textsc{Max-Duo PSM} from the viewpoint of parameterized algorithmics. More precisely, our aim is to obtain efficient algorithms when the parameter is \(k\), the number of preserved duos. Before describing previous and our results, we give a formal problem definition.

**Formal Problem Definition.** Let \(A\) and \(B\) be two strings over a finite set of symbols \(\Sigma\). Throughout this work, we assume that \(|A| = |B| = n\) and that \(A\) and \(B\) are related, that is, \(B\) is a permutation of \(A\). A mapping of \(A\) into \(B\) is a (bijective) function \(m : [n] \rightarrow [n]\) where for each \(i \in [n]\), \(A[i] = B[m(i)]\). A duo in \(A\) is a pair of consecutive positions \((i, i+1)\) of \(A\). We say that a mapping \(m\) preserves a duo \((i, i+1)\) if \(m(i)+1 = m(i+1)\). Accordingly, the \textsc{Max-Duo PSM} problem is defined as follows.

**\textsc{Max-Duo PSM}**

**Input:** Two related strings, \(A\) and \(B\), and a nonnegative integer \(k\).

**Question:** Does there exist a (bijective) mapping \(m\) of \(A\) into \(B\) such that the number of preserved duos is at least \(k\)?

**Previous Work.** Initially, \textsc{Max-Duo PSM} has been proposed as an alternative possibility of achieving approximation algorithms for \textsc{Minimum Common String Partition} (\textsc{MCSP}) [10], because the best known polynomial-time approximation algorithm has an approximation factor of \(O(\log n \log^2 n)\) [12]. Consequently, most work on \textsc{Max-Duo PSM} focuses on approximation algorithms with the first constant-factor approximation algorithm achieving an approximation factor of 4 [6]. This was subsequently improved to a factor of 3.5 [5] and then to a factor of 3.25 [7]. Recently further progress concerning the approximation factor has been reported [18, 27].

Bretta et al. [2, 1] initiated the study of \textsc{Max-Duo PSM} from the viewpoint of parameterized algorithmics. They studied both the fixed-parameter tractability and the kernelization complexity of \textsc{Max-Duo PSM}, showing that this problem can be solved in time \((8e)^{2k+o(k)} \cdot n^{O(1)}\), and that it admits a kernel of size \(O(k^4)\). Thus, Bretta et al. [2, 1] were the first to show that \textsc{Max-Duo PSM} is \textsc{FPT} and that it admits a polynomial kernel.

\[1\] We use \([n]\) as shorthand for \(\{1, 2, \ldots, n\}\).
The fixed-parameter algorithm of Bretta et al. [2, 1] is based on a combination of color coding and dynamic programming.

In comparison with MAX-Duo PSM, MCSP has been investigated more thoroughly from the viewpoint of parameterized algorithms. Damaschke [15] presented the first fixed-parameter algorithms for MCSP, for combined parameters such as “partition size ℓ plus repetition number of the input strings”. Subsequently, MCSP was shown to be fixed-parameter tractable with the single parameter partition size ℓ [9]. Jiang et al. [23] considered the combined parameter “partition size ℓ plus maximum occurrence d of any character” and showed that MCSP can be solved in time \((d!)^k \cdot n^{O(1)}\). Subsequently, this running time was improved to \(O(d^k \cdot kn)\) [8].

**Our Contribution.** We make two main contributions. First, we develop two algorithms for the MAX-Duo PSM problem that are substantially faster than the (deterministic) algorithm by Bretta et al. [2, 1], which runs in time \((8e)^{2k+o(k)} \cdot n^{O(1)}\). Specifically, we develop a randomized algorithm that solves MAX-Duo PSM in time \(4^k \cdot n^{O(1)}\), as well as a deterministic algorithm that solves this problem in time \(6.855^k \cdot n^{O(1)}\). Here, in the context of our randomized algorithm, we mean that if we determine that the input is a yes-instance, then this answer is necessarily correct, and if we determine that the input is a no-instance, then this answer is correct with probability at least 9/10. For the purpose of developing our algorithms, we present a reduction from MAX-Duo PSM to a problem of finding paths in an edge-colored graph, which might be of independent interest. This reduction lies at the heart of our algorithms, since by employing advanced tools from the field of parameterized algorithmics, namely, the methods of narrow sieves [4, 3] and representative sets [20], it is possible to quickly solve the resulting graph problem.

Second, we prove that MAX-Duo PSM admits a kernel of size \(O(k^3)\), improving upon the kernel of size \(O(k^6)\) by Bretta et al. [2].

**Preliminaries.** We use \([i, j]\) to denote the set \(\{i, i + 1, \ldots, j\}\) of natural numbers between \(i\) and \(j\). Moreover, given a string \(A\), we denote the substring starting at position \(i\) and ending at position \(j\) by \(A[i, j]\). For a (directed) graph \(G\), let \(V(G)\) denote the vertex set of \(G\) and \(E(G)\) the edge set of \(G\).

The field of parameterized algorithmics studies **parameterized problems**, where each problem instance is associated with a **parameter** \(k\), usually a nonnegative integer. Given a parameterized problem, the first question is whether the problem is **fixed-parameter tractable** (FPT), that is, whether it can be solved in time \(f(k) \cdot |X|^{O(1)}\), where \(f\) is an arbitrary function that depends only on \(k\) and \(|X|\) is the size of the input instance. In other words, the notion of FPT signifies that the combinatorial explosion can be confined to the parameter \(k\).

A second question is whether the problem also admits a **polynomial kernelization**. Here, a problem \(\Pi\) is said to admit a polynomial kernelization if there exists a polynomial-time algorithm that, given an instance \((X, k)\) of \(\Pi\), outputs an equivalent instance \((\tilde{X}, \tilde{k})\) of \(\Pi\), called a **kernel**, where \(|\tilde{X}| = k^{O(1)}\) and \(\tilde{k} \leq k\); kernelization is a mathematical concept that aims to analyze preprocessing procedures in a formal, rigorous manner. For further details, refer to [17, 14].

Due to lack of space, several proofs are deferred to an appendix.

---

2 The repetition number of a nonempty string \(x\) is defined as the largest \(i\) such that \(x = uv^i w\) where \(v\) is nonempty.

3 Clearly, the probability of success can be improved by running the algorithm multiple times and determining that the input is a yes-instance if and only if at least one of the calls determined so.
2 Reduction to a Path Finding Problem

In this section, we present a reduction from Max-Duo PSM to the following graph problem.

**LONG BLUE PATH**

**Input:** A directed acyclic graph (DAG) \(G\), an edge-coloring \(c : E(G) \rightarrow \{R, B\}\), a vertex-labeling \(\ell : V(G) \rightarrow \mathbb{N}\), and nonnegative integers \(k\) and \(r\).

**Question:** Does \(G\) contain a directed path \(P\) such that
- \(|V(P)| \leq r\),
- for all \(u, v \in V(P)\), \(\ell(u) \neq \ell(v)\), and
- \(|\{e \in E(P) : c(e) = B\}| \geq k\).

**Construction.** Let \((A, B, k)\) be an instance of Max-Duo PSM. We construct an instance \((G, c, \ell, k, r)\) of Long Blue Path as follows (here, the parameter \(k\) is the same). First, we initialize \(G\) to be an empty graph. Now, for every pair of substrings \(A[i, j]\) of \(A\) and \(B[p, q]\) of \(B\) such that \(j - i \leq k\) and \(A[i, j] = B[p, q]\), we insert a directed path \(P_{i,j,p,q}\) on \(j - i + 1\) new vertices into \(G\) whose edges are colored blue and such that the label of the \(d\)th vertex on this path is \((p + d - 1)\). The purpose of this path is to represent the possibility to preserve all duos in \(A[i, j]\) by mapping this substring to \(B[p, q]\). The labels of the vertices are meant to ensure that every position in \(B\) is mapped only once. Now, a complete mapping of \(A\) to \(B\) can be seen as a combination of mappings of substrings that are represented by the paths. Thus, we next turn to connect the paths we have just constructed by adding new edges.

For every two paths \(P_{i,j,p,q}\) and \(P'_{i',j',p',q'}\) such that \(j < i'\), we add a red edge from the last vertex of the path \(P_{i,j,p,q}\) to the first vertex of the path \(P'_{i',j',p',q'}\). Informally, the manner in which we direct these edges is meant to ensure that every position in \(A\) is mapped only once. Clearly, the resulting graph \(G\) is a DAG. Finally, we set \(r = 2k\).

**Correctness.** We first note that the construction can be done in time \(O(|V(G)| + |E(G)|)\). Now, observe that the number of paths \(P_{i,j,p,q}\) that \(G\) contains is bounded by \(n^2(k + 1)\) (as the index \(q\) equals \(p + (j - i)\)), and that each path \(P_{i,j,p,q}\) consists of at most \((k + 1)\) vertices. Hence, it holds that \(|V(G)| \leq n^2(k + 1)^2\) which directly implies \(|E(G)| < n^4(k + 1)^2\). Thus, we have the following observation.

**Observation 1.** The instance \((G, c, \ell, k, r)\) can be constructed in time \(O(n^4k^2)\).

We prove the correctness by proving two lemmata that together imply that the instances \((A, B, k)\) and \((G, c, \ell, k, r)\) are equivalent.

**Lemma 1.** If \((A, B, k)\) is a yes-instance of Max-Duo PSM, then \((G, c, \ell, k, r)\) is a yes-instance of Long Blue Path.

**Proof.** Let \(m\) be a mapping from \(A\) into \(B\) preserving at least \(k\) duos. Consider the set \(\{A_1, \ldots, A_z\}\) of substrings of \(A\) containing exactly the first \(k\) preserved duos, where we assume that \(A_1\) precedes \(A_{i+1}\) in \(A\). Consider any \(A_s\) and let \([i_s, j_s]\) be the set of positions of \(A_s\) in \(A\). Since the mapping preserves the duos in \(A_s\), there is a substring \(B[q_s, p_s]\) such that \(m(i_s + s) = q_s + s, 0 \leq s \leq j - i_s\). This implies that \(A[i_s, j_s] = B[q_s, p_s]\). Thus, \(G\) contains the path \(P_s := P_{i_s, j_s, q_s, p_s}\).

By the above, for each \(A_s\), \(G\) contains a path \(P_s\) containing \(|A_s| - 1\) blue edges. Moreover, for \(A_i\) and \(A_j\), the vertices in \(P_i\) and \(P_j\) have different labels since the mapping \(m\) is injective. Finally, there is a red edge from the last vertex of \(P_i\) to the first vertex of \(P_{i+1}\) since the last position of \(A_i\) is strictly smaller than the first position of \(A_{i+1}\). Thus, the concatenation
of $P_1, P_2$ until $P_r$ gives a path in $G$. The number of blue edges in this path is exactly $k$, and the number of vertices in this path is at most $2k$, since every $P_i$ contains at least one blue edge.

Lemma 2. If $(G, c, \ell, k)$ is a yes-instance of Long Blue Path, then $(A, B, k)$ is a yes-instance of Max-Duo PSM.

Proof. Let $P$ be a solution of the Long Blue Path instance. That is, $P$ is a path in $G$ on at most $2k$ vertices, all with different labels, containing at least $k$ blue edges. Let $\{P_1, \ldots, P_r\}$ be the set of disjoint paths obtained from $P$ by removing all red edges where we assume that there is a red edge from $P_i$ to $P_{i+1}$ for all $i \in [r-1]$. Consider some $P_2$. By the construction of $G$, $P_2 = P_{i,j,q,p}$ for some $i < j$ and $q < p$. Hence, there is a substring $A[i, j]$ of $A$ and a substring $B[q, p]$ of $B$ such that $A[i, j] = B[q, p]$. Call these two substrings the substrings of $A$ and $B$, respectively, that correspond to $P_2$. Observe that for $P_i$ and $P_j$, $i < j$, the substrings corresponding to $P_i$ and $P_j$ are disjoint: For the substrings in $A$ this is due to the fact that the indices of the corresponding substring for $P_i$ are lower than those of the substring of $A$ corresponding to $P_j$. For the substrings in $B$ this is due to the fact that the vertices in $P_i$ and $P_j$ have different labels. Thus, there is a mapping from $A$ into $B$ that maps the corresponding strings for each path $P_i$ and maps all other positions arbitrarily. The number of duos preserved by this mapping is at least $k$.

Altogether, we arrive at the following.

Lemma 3. Given an instance $(A, B, k)$ of Max-Duo PSM, an equivalent instance $(G, c, \ell, k, r)$ of Long Blue Path where $r = 2k$ can be constructed in time $O(n^4k^2)$.

3 A Randomized Algorithm based on Narrow Sieves

In this section, we adapt the method of narrow sieves that was applied to solve the $k$-Path problem [4] to solve Long Blue Path. More precisely, our objective is to provide a constructive proof for the following result.

Lemma 4. There exists a randomized algorithm that solves Long Blue Path in time $2^r \cdot r^{O(1)} \cdot |E(G)|$ and polynomial space.

In light of Lemma 3, once we have Lemma 4 at hand, we immediately obtain the following theorem.

Theorem 5. There exists a randomized algorithm that solves Max-Duo PSM in time $4^k \cdot k^{O(1)} \cdot n^4$ and polynomial space.

In the following, we focus on the proof of Lemma 4. To this end, let $(G, c, \ell, k, r)$ be an instance of Long Blue Path. Clearly, we can assume that $|V(G)| \leq |E(G)|$. To be able to rely on dynamic programming later, we need to define a notion of a partial solution:

Definition 6. Let $P$ be a directed path in $G$. Given a vertex $v \in V(G)$, $s \in [r]$ and $b \in [r] \cup \{0\}$, we say that $P$ is a $(v, s, b)$-path if the last vertex of $P$ is $v$, $|V(P)| = s$ and $\{|e \in E(P) : c(e) = B\} = b$. If for all $u, w \in V(P)$, it holds that $\ell(u) \neq \ell(v)$, then we say that $P$ is a good path.

To employ the method of narrow sieves, we need to associate labels with entities whose uniqueness should be preserved. For this purpose, we have the following definition:
Definition 7. Let \( P \) be a \((v, s, b)\)-path. Given \( f : V(P) \to [r] \), we say that \((P, f)\) is a \((v, s, b)\)-pair. If \( P \) is good, then we say that \((P, f)\) is a good pair, and if \( f \) is an injective function, then we say that \((P, f)\) is an injective pair. Given \( L \subseteq [r] \) such that the image of \( f \) is a subset of \( L \), we say that \((P, f)\) is an \( L\)-labeled pair.

Now, we define two central sets of labeled partial solutions. The first one, \( \mathcal{P} \), consists of every pair \((P, f)\) that is an injective \((v, s, b)\)-pair for some \( v \in V(G) \) and \( s, b \in [r] \) such that \( b \geq k \). The second one, \( \mathcal{Q} \), consists of every good pair \((P, f)\) in \( \mathcal{P} \). Note that for every pair \((P, f) \in \mathcal{Q}\), it holds that \( P \) is a solution for \textsc{Long Blue Path}, and for every solution \( P \) for \textsc{Long Blue Path}, by letting \( f \) be a function that assigns \( i \) to the \( i \)th vertex on \( P \), we obtain a pair \((P, f) \in \mathcal{Q}\). Thus, we have the following observation.

Observation 2. The instance \((G, c, \ell, k, r)\) is a yes-instance if and only if \( \mathcal{Q} \neq \emptyset \).

With these definitions at hand, we may describe the rough idea of the approach. We represent which edges are used by \((v, s, b)\)-pair.

Observation 3. For all \((P, f) \in \mathcal{Q}\), there does not exist \((P', f') \in \mathcal{P} \setminus \{(P, f)\}\) such that \( \text{mon}(P, f) = \text{mon}(P', f') \).

The following lemma will be used to show that the partial solutions of \( \mathcal{P} \setminus \mathcal{Q} \) cancel each other out.

Lemma 10. There exists a function \( g : \mathcal{P} \setminus \mathcal{Q} \to \mathcal{P} \setminus \mathcal{Q} \) such that for all \((P, f) \in \mathcal{P} \setminus \mathcal{Q}\), it holds that \( \text{mon}(P, f) = \text{mon}(g(P, f)), g(P, f) \neq (P, f), \) and \( g(g(P, f)) = (P, f) \).

Proof. Let \(<\) be some order on \( \{\{u, v\} : u, v \in V(P)\} \). Given \((P, f) \in \mathcal{P} \setminus \mathcal{Q}\), define \( \text{rep}(P, f) = \{\{u, v\} : u, v \in V(P), u \neq v, \ell(u) = \ell(v)\} \). Since \( P \) is not a good path, it holds that \( \text{rep}(P, f) \neq \emptyset \). Hence, it is well defined to let \( \{u, v\} \) be the smallest set in \( \text{rep}(P, f) \) according to \(<\). We let \( h \) be defined as \( f \) except that \( h(u) = f(v) \) and \( h(v) = f(u) \). Now, we
set \( g(P,f) = (P,h_{P,f}) \). Clearly, \( g(P,f) \in \mathcal{P} \). Note that \( \text{rep}(P,f) = \text{rep}(P,h_{P,f}) \), and hence \( g(P,f) \notin \mathcal{Q} \) and \( g(P,f)) = (P,f) \). Since \( (P,f) \in \mathcal{P} \), it holds that \( f \) is an injective function; therefore \( f(v) \neq f(u) \), which implies that \( g(P,f) \neq (P,f) \). Finally, since \( \ell(u) = \ell(v) \), it holds that \( \text{mon}(P,f) = \text{mon}(g(P,f)) \).

Let \( \mathbb{F} \) be a field of characteristic 2 (to be determined). From now on, we suppose that \( \text{POL} \) is evaluated over \( \mathbb{F} \). Notice that

\[
\text{POL} = \sum_{(P,f) \in \mathcal{Q}} \text{mon}(P,f) + \sum_{(P,f) \in \mathcal{P} \setminus \mathcal{Q}} \text{mon}(P,f).
\]

Suppose that \( \text{POL} \) is evaluated over \( \mathbb{F} \). By Lemma 10, we have that \( \text{POL} = \sum_{(P,f) \in \mathcal{Q}} \text{mon}(P,f) \). Then, by Observation 3, we have that \( \text{POL} \) is not identically 0 if and only if \( \mathcal{Q} \) is not empty. Hence, by Observation 2, we have the following lemma.

\[\textbf{Lemma 11.}\] The instance \((G, c, \ell, k, r)\) is a yes-instance if and only if \( \text{POL} \) is not identically 0.

In light of Lemma 11, our task is to determine whether \( \text{POL} \) is identically 0. For this purpose, we need the following notation. Given \( v \in V(G), s \in [r], b \in [r] \cup \{0\} \) and \( L \subseteq [r] \), let \( \mathcal{P}_{v,s,b,L} \) denote the set of every \( L \)-labeled \((v,s,b)\)-pair \((P,f)\), and \( \text{POL}_{v,s,b,L} = \sum_{(P,f) \in \mathcal{P}_{v,s,b,L}} \text{mon}(P,f) \). Moreover, denote

\[
\mathcal{P}_L = \bigcup_{v \in V(G), s \in [r], b \geq k} \mathcal{P}_{v,s,b,L},
\]

and \( \text{POL}_L = \sum_{(P,f) \in \mathcal{P}_L} \text{mon}(P,f) \). By the principle of inclusion-exclusion, we have that

\[
\text{POL} = \sum_{L \subseteq [r]} (-1)^{r - |L|} |\text{POL}_L|.
\]

Then, since \( \mathbb{F} \) is a field of characteristic 2 (refer to [4] for further details) we obtain the following.

\[\textbf{Observation 4.}\] \( \text{POL} = \sum_{L \subseteq [r]} \text{POL}_L \).

Hence, to determine whether \( \text{POL} \) is identically 0, it is sufficient to determine whether \( \sum_{L \subseteq [r]} \text{POL}_L \) is identically 0. To proceed, we need to recall the following well-known lemma.

\[\textbf{Lemma 12 ([24, 28, 16]).}\] Let \( p(x_1, x_2, \ldots, x_n) \) be a nonzero polynomial of total degree at most \( d \) over a finite field \( \mathbb{K} \). Then, for \( a_1, a_2, \ldots, a_n \in \mathbb{K} \) selected independently and uniformly at random, \( \Pr(p(a_1, a_2, \ldots, a_n) \neq 0) \geq 1 - d/|\mathbb{K}| \).

Notice that \( \text{POL} \) is a polynomial of total degree at most \( 2r \). Therefore, by setting \( |\mathbb{F}| = 2^{\log(20r)} \), from Lemma 11, Observation 4, and Lemma 12, we have that

\[\textbf{Lemma 13.}\] For a random assignment to all variables \( x_{i,j} \) and \( y_c \), if \((G, c, \ell, k, r)\) is a no-instance, then \( \sum_{L \subseteq [r]} \text{POL}_L \) evaluates to 0, and otherwise it does not evaluate to a 0 with probability at least \( 9/10 \).

In light of Lemma 13, to conclude that Lemma 4 is correct, it is sufficient to prove the following result.
Lemma 14. Given $L \subseteq \{r\}$ and an assignment to all variables $x_{i,j}$ and $y_e$, the polynomial $POL_L$ can be evaluated in time $r^{O(1)} \cdot |E(G)|$.

Finally, we would like to remark that if one is interested in finding a mapping that is a solution rather than just determining whether such a mapping exists, this goal can be achieved by standard means of self-reduction. Briefly, if $k$ is not positive, then we are done. Else, if the algorithm determines that there exists a solution, then we may “guess” (i.e., perform exhaustive search) a longest substring $A'$ of $A$ that is mapped by some solution while preserving all duos in $A'$ as well as the substring $B'$ of $B$ to which it is mapped. If our guess is correct, then the symbol preceding $A'$ in $A$ is not equal to the symbol preceding $B'$ in $B$ and the symbol after $A'$ in $A$ is also not equal to the symbol after $B'$ in $B$ (if such symbols exist). Then, we may replace $A'$ and $B'$ in $A$ and $B$, respectively, by some new symbol, decrease $k$ by $|A'| - 1$, and call the algorithm recursively. Notice that the length of $A'$ should be at least 2, and hence the size of the input has decreased.

4 Deterministic Algorithm: Representative Sets

In this section, we adapt the approach in which the method of representative sets is applied to solve the $k$-Path problem [20]. More precisely, our objective is to provide a constructive proof for the following result.

Lemma 15. There exists a deterministic algorithm that solves Long Blue Path in time $O((1+\sqrt{5})^{r+o(r)} \cdot |E(G)| \cdot \log |E(G)|)$.

Combining Lemma 3 and 15 gives us the following.

Theorem 16. There exists a deterministic algorithm that solves Max-Duo PSM in time $O((1+\sqrt{5})^k \cdot n^4 \log n) = O(6.855^k \cdot n^4 \log n)$.

5 A Cubic Problem Kernel

In this section we will show that Max-Duo PSM admits a kernel of size $O(k^3)$. Let $(A, B, k)$ be an instance of Max-Duo PSM, and let $S \in \{A, B\}$. If $S = A$, then we let $S = B$. Analogously, if $S = B$, then we let $S = A$.

Let $m$ be a map of $S$ into $\overline{S}$, and let $D$ be a set of duos. We denote by $m(D) = \{(m(i), m(i+1)) \mid (i, i+1) \in D\}$ the image of $D$ under $m$. We say that $m$ preserves $D$ if $m$ preserves each duo in $D$. Let $C_A$ and $C_B$ be sets of duos. We say that the pair $(C_A, C_B)$ is complete for $(A, B, k)$ if whenever there is a map $m$ of $A$ into $B$ that preserves $k$ duos, then there is a subset $D \subseteq C_A$ with $|D| = k$ and a map $m'$ such that $m'$ preserves $D$ and $m'(D) \subseteq C_B$. The size of $(C_A, C_B)$ is defined as $|C_A| + |C_B|$. Let $f : \mathbb{N} \to \mathbb{N}$ be a function. A complete pair $(C_A, C_B)$ of size $f(k)$ for $(A, B, k)$ can be used to construct a kernel $(A', B', k)$ of size $O(f(k))$ for $(A, B, k)$.

Theorem 17 ([2, Section 4.2]). Let $(C_A, C_B)$ be a complete pair of size $f(k)$ for $(A, B, k)$. Then one can construct in time $O(f(k))$ related strings $A'$ and $B'$, each of size $O(f(k))$ such that $(A, B, k)$ is a yes-instance of Max-Duo PSM if and only if $(A', B', k)$ is a yes-instance of Max-Duo PSM.

Using Theorem 17, it is sufficient to show that one can obtain in polynomial time a complete pair $(C_A, C_B)$ for $(A, B, k)$ of size $O(k^3)$. 

A block of size $s$ is a set $X = \{(i, i + 1), (i + 1, i + 2), \ldots, (i + s - 1, i + s)\}$ consisting of $s$ consecutive duos. We say that $(i, i + 1)$ is the root of $X$. If $S$ is a string of length at least $i + s$, then we let $\text{str}(S, X) = S[i, i + s]$ be the substring of $S$ corresponding to the positions that occur in $X$. The following observation is immediate.

\begin{observation}
Let $(A, B, k)$ be an instance of Max-Duo PSM and let $m$ be a map of $A$ into $B$ that preserves a block $X$ of size $k$. Then $(A, B, k)$ is a yes-instance of Max-Duo PSM. Additionally, the instance $(A', B', k)$ where $A' = \text{str}(A, X)$ and $B' = \text{str}(B, m(X))$ is also yes-instance of Max-Duo PSM.
\end{observation}

In the remainder of this section we assume that no map $m$ of $A$ into $B$ preserves a block of size $k$. Our algorithm is based on the notion of rare duo, which we define next. For each two symbols $a, b \in \Sigma$, and each string $S \in \{A, B\}$, we let

$$n(S, a, b) := |\{i : 1 \leq i \leq |S| - 1, S[i, i + 1] = ab\}|$$

be the number of occurrences of the length-two string $ab$ as a substring of $S$. We say that a length-two string $ab$ is rare for $S$ if $ab$ occurs as a substring of both $S$ and $\overline{S}$ and $n(S, a, b) \leq n(\overline{S}, a, b)$. Observe that if $ab$ occurs as many times in $S$ as it occurs in $\overline{S}$, then $ab$ is rare for both $S$ and $\overline{S}$. We say that a duo $(i, i + 1)$ is rare for $S$ if $S[i, i + 1]$ is rare for $S$. We let $\text{rare}(S)$ be the set of duos that are rare for $S$.

\begin{lemma}
If either $|\text{rare}(A)| \geq 4k$ or $|\text{rare}(B)| \geq 4k$, then $(A, B, k)$ is a yes-instance.
\end{lemma}

\textbf{Proof.} The duo graph associated with $A$ and $B$ is the bipartite graph $G(A, B) = (V_A \cup V_B, E)$ defined as follows:

$$V_A = \{(i, i + 1) \mid 1 \leq i \leq n - 1\},$$

$$V_B = \{(j, j + 1) \mid 1 \leq j \leq n - 1\},$$

$$E = \{[(i, i + 1), (j, j + 1)] \mid A[i] = B[j], A[i + 1] = B[j + 1]\}.$$ 

Intuitively, each of the sets $V_A$ and $V_B$ contains all pairs of consecutive positions from $[n]$. A duo $(i, i + 1)$ in $V_A$ is connected to a duo $(j, j + 1)$ in $V_B$ if and only if the length-two string $A[i]A[i + 1]$ is equal to $B[j]B[j + 1]$.

If $e = [(i, i + 1), (j, j + 1)]$ is an edge of $G(A, B)$, then we say that $(i, i + 1)$ is the left endpoint of $e$ and $(j, j + 1)$ is the right endpoint of $e$. If $M$ is a matching in $G(A, B)$, then we let $M_A$ be the set of duos in $V_A$ that are left endpoints of edges in $M$, and $M_B$ be the set of duos in $V_B$ that are right endpoints of edges in $M$.

Assume that either $|\text{rare}(A)| \geq 4k$ or $|\text{rare}(B)| \geq 4k$. Then $G$ contains a matching of size at least $4k$. Let $\mathbf{M}$ be a maximum matching in $G(A, B)$.

It has been shown in [6] that given a matching $\mathbf{M}$ of size at least $4k$ for the graph $G(A, B)$, one can construct a sub-matching $\mathbf{M}$ of $\mathbf{M}$ of size at least $k$ such that $\mathbf{M}$ directly gives a map preserving at least $k$ duos. Therefore, the instance is a yes-instance in this case.

In the remainder of this section we thus assume that there are less than $4k$ duos that are rare for $A$, and less than $4k$ duos that are rare for $B$. This implies that we may add all rare duos to the sets $C_A$ and $C_B$ without surpassing the desired size bound of $O(k^3)$.

Let $S$ be a string in $\{A, B\}$. We say that a duo $(j, j + 1)$ is a match for a duo $(i, i + 1)$ in $\overline{S}$ if there exists a map $m$ of $S$ into $\overline{S}$ that preserves $(i, i + 1)$, and $(m(i), m(i + 1)) = (j, j + 1)$. If $X$ and $Y$ are blocks, then we say that $Y$ is a match for $X$ in $\overline{S}$ if there exists a map $m$ of $S$ into $\overline{S}$ such that $m$ preserves $X$, and $m(X) = Y$. 

\begin{comment}

$$\text{str}(X) = X[i, i + s] = \text{str}(S, X)$$

\end{comment}
We now turn to the second type of matched pairs of blocks, those where one block contains a selection of roots of matches for $S$. This observation is useful because it tells us that for each match in a map, one of the two duos must be in the ball of radius $X$ and since $\text{roots}(S, i, i + 1)$ is not rare, we add all pairs of matched blocks that both contain at least one nonrare duo. To this end, for each $i, i + 1$ can add all duos of these blocks by considering a sufficiently large neighborhood of all rare duos. The following lemma essentially implies that by adding the ball of radius $X$ around each rare duo, we essentially pick up one half of each match. We now consider two types of matched blocks that may occur in the solution. First, there may be pairs of matched blocks $S, i, i + 1$, that is, strictly more often in $S$ than it occurs in $\overline{S}$. In other words, $n(S, a, b) > n(\overline{S}, a, b)$. This implies that $(j, j + 1)$ is rare for $\overline{S}$. This observation is useful because it tells us that for each match in a map, one of the two duos is rare, so by adding all the rare duos to $C_A$ and $C_B$, we essentially pick up one half of each match. We now consider two types of matched blocks that may occur in the solution. First, there may be pairs of matched blocks $X$ and $Y$ that both contain nonrare duos. We can add all duos of these blocks by considering a sufficiently large neighborhood of all rare duos. To this end, for each $i, i + 1$ denote the ball of radius $k$ around the duo $(i, i + 1)$.

\begin{algorithm}
\begin{algorithmic}[1]
\Procedure{Roots}{$S, i, i + 1$}
\State $R = \emptyset$
\State $k' \leftarrow$ size of the maximal block which is rooted at $(i, i + 1)$, rare for $S$, and has a match in $\overline{S}$. Note that $k' \leq k - 1$.
\For{$\ell = k'$ to $1$}
\State $X \leftarrow$ unique block of size $\ell$ rooted at $(i, i + 1)$
\For{$j = 1$ to $n - 1$}
\If{$|R| < 2k - 1$ and $|j' - j| > k \\forall j' \in R$ and $(j, j + 1)$ is a root for a match of $X$ in $\overline{S}$ then}
\State $R \leftarrow R \cup \{(j, j + 1)\}$
\EndIf
\EndFor
\EndFor
\State \Return $R$
\EndProcedure
\end{algorithmic}
\end{algorithm}

\begin{itemize}
\item \textbf{Observation 6.} Let $S \in \{A, B\}$ and let $(j, j + 1)$ be a match for $(i, i + 1)$ in $\overline{S}$. Then if $(i, i + 1)$ is not rare for $S$, $(j, j + 1)$ is rare for $\overline{S}$.
\end{itemize}

\begin{proof}
Since $(j, j + 1)$ is a match for $(i, i + 1)$ in $\overline{S}$, there is some length-two string $ab$ such that $S[i]S[i + 1] = \overline{S}[j][j + 1] = ab$. Since $(i, i + 1)$ is not rare for $S$, the string $ab$ occurs strictly more often in $S$ than it occurs in $\overline{S}$. In other words, $n(S, a, b) > n(\overline{S}, a, b)$. This implies that $(j, j + 1)$ is rare for $\overline{S}$.\end{proof}

This observation is useful because it tells us that for each match in a map, one of the two duos is rare, so by adding all the rare duos to $C_A$ and $C_B$, we essentially pick up one half of each match. We now consider two types of matched blocks that may occur in the solution. First, there may be pairs of matched blocks $X$ and $Y$ that both contain nonrare duos. We can add all duos of these blocks by considering a sufficiently large neighborhood of all rare duos. To this end, for each $i, i + 1$, let

$$B_k(i) = \{(i', i' + 1) \mid i' \in \{1, ..., n - 1\}, i - k \leq i' \leq i + k\}$$

denote the ball of radius $k$ around the duo $(i, i + 1)$

The following lemma essentially implies that by adding the ball of radius $k$ around each rare duo, we add all pairs of matched blocks that both contain at least one nonrare duo.

\begin{itemize}
\item \textbf{Lemma 19.} Let $S \in \{A, B\}$, $X$ be a block of size at most $k - 1$ containing a duo $(i, i + 1)$ that is not rare for $S$, and let $m$ be a map of $S$ into $\overline{S}$ such that $X$ is preserved by $m$. Then $(m(i), m(i + 1))$ is rare for $\overline{S}$ and $m(X) \subseteq B_k(m(i))$.
\end{itemize}

\begin{proof}
Since $(i, i + 1)$ is preserved by $m$, $(m(i), m(i + 1))$ is a match for $(i, i + 1)$ in $\overline{S}$. Since $(i, i + 1)$ is not rare for $S$, by Observation 6, $(m(i), m(i + 1))$ is rare for $\overline{S}$. Since $m$ preserves $X$ and since $|X| \leq k - 1$, $m(X)$ is a block of size at most $k - 1$. Therefore, all duos in $m(X)$ must be in the ball of radius $k$ around $(m(i), m(i + 1))$, that is, $m(X) \subseteq B_k(m(i))$.\end{proof}

We now turn to the second type of matched pairs of blocks, those where one block $X$ of $S$ has only rare duos for $S$; we call such a block $X$ rare. Since $X$ is rare, it is rooted at some rare duo $(i, i + 1)$. To obtain the complete set, we need to add duos in $\overline{S}$. This is done by the procedure $\text{Roots}$ which receives as input a string $S$ and a duo in $S$ and returns a set of duos $\text{Roots}(S, i, i + 1)$. Intuitively, for each block $X$ that is rare for $S$ and rooted at $(i, i + 1)$, the set $\text{Roots}(S, i, i + 1)$ contains a selection of roots of matches for $X$ in the string $\overline{S}$. This selection is made
according to two criteria. First, roots of matches for larger blocks are added first. Second, the roots in $\text{ROOTS}(S, i, i + 1)$ are sufficiently far apart from each other. Now consider the set

$$F(S, i, i + 1) = \bigcup_{(j,j+1) \in \text{ROOTS}(S,i,i+1)} B_k(j).$$

Intuitively, $F(S, i, i + 1)$ consists of all duos that are sufficiently close to duos in $\text{ROOTS}(S, i, i + 1)$. The next lemma states that if some map $m$ of $S$ into $\mathcal{S}$ preserves some block $X$ that is rooted at $(i, i + 1)$ and rare for $S$, then this map can be transformed into a map $m'$ that preserves $X$, that sends $X$ to $F(S, i, i + 1)$, and that is equal to $m$ on every duo outside $X$.

**Lemma 20.** Let $m$ be a map of $S$ into $\mathcal{S}$, $D$ be a set of duos such that $|D| = k$, and $X \subseteq D$ be a block that is rooted at $(i, i + 1)$, that is rare for $S$ and that is preserved by $m$. Then there is a map $m'$ of $S$ into $\mathcal{S}$ such that $X$ is preserved by $m'$, such that $m'(X) \subseteq F(S, i, i + 1)$ and such that $(m'(i''), m'(i' + 1)) = (m(i''), m(i' + 1))$ for each $(i', i' + 1) \in D \setminus X$.

**Proof.** Let $(j, j + 1)$ be the root of $m(X)$ in $\mathcal{S}$. Let $n(S, X)$ be the number of duos in $\text{ROOTS}(S, i, i + 1)$ that are roots of matches for $X$ in $\mathcal{S}$. Suppose that $n(S, X) < 2k - 1$. Then either $(j, j + 1) \in \text{ROOTS}(S, i, i + 1)$ or $(j, j + 1) \not\in \text{ROOTS}(S, i, i + 1)$ and there exists some duo $(j', j' + 1) \in \text{ROOTS}(S, i, i + 1)$ with $|j' - j| < k$. Note that if this were not the case, the duo $(j, j + 1)$ would have been added to $\text{ROOTS}(S, i, i + 1)$, since all three conditions of the 'if' instruction of Algorithm 1 would have been satisfied. In any case, $m(X) \subseteq B_k(j') \subseteq F(S, i, i + 1)$. Therefore, if $n(S, X) < 2k - 1$, we may simply set $m' = m$.

Now assume that $n(S, X) = 2k - 1$. Note that for each duo $(j, j + 1)$ there are no three distinct $j_1, j_2$ and $j_3$ such that $(j_i, j_i + 1) \in \text{ROOTS}(S, i, i + 1)$ and $(j, j + 1) \in B(j_i)$ for $i \in \{1, 2, 3\}$. In other words $(j, j + 1)$ can intersect at most two balls of radius $k$ rooted at duos in $\text{ROOTS}(S, i, i + 1)$. Therefore, since $|D \setminus X| \leq k - 1$, the set $D \setminus X$ intersects at most $2k - 2$ balls of radius $r$ rooted at duos in $\text{ROOTS}(S, i, i + 1)$. In other words, there is at least one $(j', j' + 1) \in \text{ROOTS}(S, i, i + 1)$ that is the root of a match for $X$ in $S$ and such that $B_k(j') \cap (D \setminus X) = \emptyset$. Therefore, we may set $m'$ as the map of $S$ into $\mathcal{S}$ that preserves $X$, that sends the root of $X$ to $(j', j' + 1)$, and that is equal to $m$ on every duo $(i', i' + 1) \in D \setminus X$. ▶

Now, for each $S \in \{A, B\}$, consider the following set $C_S$ of duos.

$$C_S = \bigcup_{(i,i+1) \in \text{rare}(S)} B_k(i) \cup \bigcup_{(i,i+1) \in \text{rare}(\mathcal{S})} F(\mathcal{S}, i, i + 1).$$

(1)

In other words, for each duo $(i, i + 1)$ that is rare for $S$, $C_S$ contains all duos in the ball of radius $k$ around $(i, i + 1)$. Moreover, for each duo $(i, i + 1)$ that is rare for $\mathcal{S}$, $C_S$ contains all duos in the set $F(\mathcal{S}, i, i + 1)$. The following lemma states that if a map $m$ of $S$ into $\mathcal{S}$ preserves a set $D$ containing $k$ duos, then there exists a map $m'$ that also preserves $D$ in such a way that $m'(D) \subseteq C_S$.

**Lemma 21.** Let $D$ be a set of duos such that $|D| = k$. Let $m$ be a map of $S$ into $\mathcal{S}$ that preserves all duos in $D$. Then there is a map $m'$ of $S$ into $\mathcal{S}$ that preserves all duos in $D$, and such that $m'(D) \subseteq C_S$.

**Proof.** Let $X_1, \ldots, X_r$ be the set of rare blocks that are contained in $D$ and that are maximal with respect to set inclusion. In other words, for each $j \in \{1, \ldots, r\}$ and each $Y$ such that $X_j \subseteq Y \subseteq D$, we have that $Y$ is not a rare block. Note that since these blocks are rare and
maximal, they are pairwise disjoint, i.e., $X_j \cap X_{j'} = \emptyset$ for $j \neq j'$. For each $j \in \{1, \ldots, r\}$ let $(i_j, i_j + 1)$ be the root of $X_j$ and $D_j = D \setminus X_j$. Additionally, let $D' = D \setminus \bigcup_{j=1}^r X_j$. Note that $D' \subseteq D_j$ for each $j \in \{1, \ldots, r\}$.

Let $m_0, m_1, \ldots, m_r$ be maps of $S$ into $\mathcal{S}$ defined inductively as follows. First, we set $m_0 = m$. Now, for each $j \in \{1, \ldots, r\}$, we let $m_j$ be a map of $S$ into $\mathcal{S}$ constructed according to Lemma 20. More precisely, $m_j$ preserves $X_j$, $m_j(X_j) \subseteq F(S, i_j, i_j + 1)$, and $(m_j(i), m_j(i + 1)) = (m_{j-1}(i), m_{j-1}(i + 1))$ for each duo $(i, i + 1) \in D_j = D \setminus X_j$.

Using the maps $m_0, m_1, \ldots, m_r$ defined above, it follows by induction on $j$ that for each $l \in \{1, \ldots, r\}$, $m_l(X_l) \subseteq F(S, i_l, i_l + 1) \subseteq \mathcal{C}_S$ and $(m_l(i), m_l(i + 1)) = (m(i), m(i + 1))$ for each $(i, i + 1) \in D'$. In particular, for each $l \in \{1, \ldots, r\}$, $m_l(X_l) \subseteq F(S, i_l, i_l + 1) \subseteq \mathcal{C}_S$ and $(m_l(i), m_l(i + 1)) = (m(i), m(i + 1))$ for each $(i, i + 1) \in D' \subseteq D_j$. This shows, that $m_r$ preserves $D$, and sends $\bigcup_{j=1}^r X_j$ to a subset of $\mathcal{C}_S$ and agrees with $m$ in every duo in $D' = D \setminus \bigcup_{j=1}^r X_j$.

Let $m = m_r$. It remains to show that $m'$ also sends blocks that are not rare for $S$ to subsets of $\mathcal{C}_S$. Let $X'_1, \ldots, X'_s$ be the maximal blocks that are contained in $D$ and that are not rare for $S$. Note that these blocks are indeed contained in $D'$ and form a partition of $D'$. Since for each $j \in \{1, \ldots, s\}$, $X'_j$ has at least one duo $(i, i + 1)$ that is not rare for $S$, Lemma 19 implies that $(m'(i), m'(i + 1))$ is rare for $\mathcal{S}$ and that $m'(X'_j) \subseteq B_k(m'(i)) \subseteq \mathcal{C}_S$. Since $X'_1, \ldots, X'_s$ forms a partition of $D'$, $m'(D') \subseteq \mathcal{C}_S$. Since by the discussion above, $m'(\bigcup_{j=1}^r X_j)$ is also a subset of $\mathcal{C}_S$, we have that $m'(D) \subseteq \mathcal{C}_S$.

Let $C_A$ and $C_B$ be sets of duos constructed according to Equation 1. We can show that $(C_A, C_B)$ is complete for $(A, B, k)$ by applying Lemma 21 twice. More precisely, once with respect to maps of $A$ into $B$, and once with respect to maps of $B$ into $A$.

**Lemma 22.** The pair $(C_A, C_B)$ is complete for $(A, B, k)$.

**Proof.** Let $D_1$ be a set of duos of size $k$. Let $m_1$ be a map of $A$ into $B$ which preserves all duos in $D_1$. Then by Lemma 21 there is a map $m_2$ of $A$ into $B$ which also preserves all duos in $D_1$, but with the property that $m_2(D_1) \subseteq C_B$. Now let $D_2 = m_2(D_1)$, and $m_3 = m_2^{-1}$ be the inverse of $m_2$. In other words, $m_3$ is a map of $B$ into $A$ such that for each $i \in [n]$, $m_2(i) = j$ if and only if $m_3(j) = i$. Then $m_3$ preserves all duos in $D_2$. By Lemma 21 there is a map $m_4$ of $B$ into $A$ that also preserves all duos in $D_2$ but with the additional property that $m_4(D_2) \subseteq C_A$.

Let $D_3 = m_4(D_2)$, and let $m_5 = m_4^{-1}$ be the inverse of $m_4$. Then $m_5$ is a map of $A$ into $B$ that preserves $D_3 \subseteq C_A$ and such that $m_5(D_3) = D_2 \subseteq C_B$. Since $|D_3| = |D_2| = k$, the pair $(C_A, C_B)$ is complete for $(A, B, k)$.

Now, we can upper-bound the size of $C_S$ and the time needed to construct $C_S$, thus arriving at our main theorem.

**Theorem 23.** Given an instance $I = (A, B, k)$ of MAX-Duo PSM, one can construct in time $O(|\Sigma|^l \cdot n \cdot k^3 \cdot \cdot |A|)$ an instance $I' = (A', B', k)$ of MAX-Duo PSM with $|A'|$ and $|B'|$ bounded by $O(k^3)$ such that $I$ is a yes-instance if and only if $I'$ is a yes-instance.

A Proofs of Section 3

Lemma 14. Given $L \subseteq [r]$ and an assignment to all variables $x_{i,j}$ and $y_e$, the polynomial $POL_L$ can be evaluated in time $O(r^{O(1)} \cdot |E(G)|)$.

Proof Sketch. The evaluation can be performed by a simple procedure based on dynamic programming. For the sake of completeness, we present the base cases and recursive formula below. For simplicity, we abuse notation by using the symbols $x_{i,j}$ and $y_e$ to refer to the values assigned to the variables $x_{i,j}$ and $y_e$, respectively.

The procedure uses a table $M$, which has an entry $M[v,s,b]$ for all $v \in V(G)$, $s \in [r]$ and $b \in [r] \cup \{0\}$. The purpose of this entry is to store the evaluation of $POL_{v,s,b,L}$. Then, the
evaluation of \( POL_L \) is given by
\[
\sum_{v \in V(G), \quad s, b \in [r], b \geq k} M[v, s, b].
\]

The basis consists of the following cases:
- If \( b \geq s \), then \( M[v, s, b] = 0 \).
- Else if \( s = 1 \), then \( M[v, s, b] = \sum_{i \in L} x_{(v), i} \).

Now, consider an entry \( M[v, s, b] \) not computed in the basis. We assume that a reference to an undefined entry returns 0. Then,
\[
M[v, s, b] = \sum_{(u, v) \in E(G), \quad c(u, v) = R} \left( \sum_{i \in L} x_{(v), i} \cdot y_{(u, v)} \cdot M[u, s - 1, b] \right)
+ \sum_{(u, v) \in E(G), \quad c(u, v) = B} \left( \sum_{i \in L} x_{(v), i} \cdot y_{(u, v)} \cdot M[u, s - 1, b - 1] \right).
\]

\[\blacktriangleright\]

**B Proofs of Section 4**

In this section, we adapt the approach in which the method of representative sets is applied to solve the \textit{k-Path} problem \cite{20}. More precisely, our objective is to provide a constructive proof for the following result.

\[\blacktriangleright\textbf{Lemma 15.} \textit{There exists a deterministic algorithm that solves Long Blue Path in time} \quad O((1 + \sqrt{5})^{r+o(r)} \cdot |E(G)| \log |E(G)|).\]

In light of Lemma 3, once we have Lemma 15 at hand, we directly obtain the following theorem.

\[\blacktriangleright\textbf{Theorem 16.} \textit{There exists a deterministic algorithm that solves Max-Duo PSM in time} \quad O((1 + \sqrt{5})^{2k+o(k)} \cdot n^4 \log n) = O(6.855^k \cdot n^4 \log n).\]

Next, we focus on the proof of Lemma 15. To this end, let \((G, c, \ell, k, r)\) be an instance of \textit{Long Blue Path}. Without loss of generality, we can assume that the image of \( \ell \) is a subset of \([|V(G)|]\) and that \(|V(G)| \leq |E(G)|\). Here, a \textit{p-set} is a set of size \( p \). To describe our algorithm, we need to present the definition of a representative family.

\[\blacktriangleright\textbf{Definition 27 \cite{20}}. \textit{Given a universe} \( U \) \textit{and a family} \( S \) \textit{of p-subsets of} \( U \), \textit{we say that a subfamily} \( \hat{S} \subseteq S \) \textit{t-represents} \( S \) \textit{if for every pair of sets} \( X \subseteq S \), \textit{and} \( Y \subseteq U \setminus X \) \textit{of size} \( t - p \), \textit{there exists a set} \( \hat{X} \in \hat{S} \) \textit{such that} \( \hat{X} \cap Y = \emptyset \).

The papers \cite{20} and \cite{25} present an algorithm, to which we refer as \textit{RepAlg}, that given a universe \( U \) and a family \( S \) of \textit{p-subsets of} \( U \), computes a subfamily \( \hat{S} \subseteq S \) of size \( S(|U|, t, p) \) that \( t \)-represents \( S \) in time \( |S| \cdot T(|U|, t, p) \), such that the following condition is satisfied:
\[
\sum_{p=1}^{t} |U| \cdot S(|U|, t, p - 1) \cdot T(|U|, t, p) = \left( \frac{1 + \sqrt{5}}{2} \right)^{t+o(t)} \cdot |U| \log |U|.
\]

We proceed by presenting a procedure that is based on a combination of dynamic programming and calls to \textit{RepAlg}. For this purpose, we use a table \( M \) that has an entry
\[ M[v, s, b] \text{ for all } v \in V(G), s \in [r] \text{ and } b \in [r] \cup \{0\}. \] Let \( \mathcal{P}_{v,s,b} \) denote the set of all good \((v, s, b)\)-paths (see Definition 6). Give a \((v, s, b)\)-path, define \( \ell(P) = \{\ell(v) : v \in V(P)\} \).

Moreover, define \( \mathcal{S}_{v,s,b} = \{\ell(P) : P \in \mathcal{P}_{v,s,b}\} \). The purpose of the entry \( M[v, s, b] \) would be to store a subfamily of \( \mathcal{S}_{v,s,b} \) that \( r \)-represents it. Next, we show how to compute the entries of \( M \). Here, the calls to \( \text{RepAlg} \) correspond to the universe \([|E(G)|]\) and with \( t = r \).

The basis consists of the following cases:
- If \( s = 1 \) but \( b \neq 0 \), then \( M[v, s, b] = \emptyset \).
- Else if \( s = 1 \), then \( M[v, s, b] = \{\{\ell(v)\}\} \).

Now, consider an entry \( M[v, s, b] \) not computed in the basis. We assume that a reference to an undefined entry returns an empty set. Then, we first compute the two following families.
- \( \mathcal{A}_{v,s,b} = \{X \cup \{\ell(v)\} : (u, v) \in E(G), c(u, v) = R, X \in M[u, s-1, b], \ell(v) \notin X\} \).
- \( \mathcal{B}_{v,s,b} = \{X \cup \{\ell(v)\} : (u, v) \in E(G), c(u, v) = B, X \in M[u, s-1, b-1], \ell(v) \notin X\} \).

Accordingly, we compute \( M[v, s, b] \) as follows.

\[ M[v, s, b] = \text{RepAlg}(\mathcal{A}_{v,s,b} \cup \mathcal{B}_{v,s,b}) \]

First, note that the entire computation can be performed in time

\[
O\left( \sum_{v \in V(G)} \sum_{s=1}^{r} \sum_{b=0}^{r} \sum_{(u, v) \in E(G)} S(|E(G)|, r, s) \cdot T(|E(G)|, r, s) \right)
\]

\[ = O\left( \sum_{r=1}^{\infty} |E(G)| \cdot S(|E(G)|, r, s) \cdot T(|E(G)|, r, s) \right) \]

Thus, we have the following observation.

\[ \text{Observation 7. The table } M \text{ is computed in time } O\left( \frac{1+\sqrt{5}}{2} t^{1+o(r)} \cdot |E(G)| \log |E(G)| \right) \]

Next, we prove that the computation of \( M \) is correct.

\[ \text{Lemma 28. The computation of } M \text{ ensures that for all } v \in V(G), s \in [r] \text{ and } b \in [r] \cup \{0\}, M[v, s, b] \text{ } r\text{-represents } \mathcal{S}_{v,s,b}. \]

\textbf{Proof.} We prove the statement by induction on \( s \). In the basis, where \( s = 1 \), it is clear that \( M[v, s, b] \) is simply assigned \( \mathcal{S}_{v,s,b} \), and therefore it also 1-represents \( \mathcal{S}_{v,s,b} \). Now, fix some \( s \geq 2 \), and suppose that the statement is correct for \( s - 1 \). To prove that the statement is correct for \( s \), choose some \( v \in V(G), b \in [r] \cup \{0\}, X \in \mathcal{S}_{v,s,b} \) and \( Y \subseteq |E(G)| \setminus X \) such that \( |Y| = r - s \). We need to show that there exists \( \tilde{X} \in M[v, s, b] \) such that \( \tilde{X} \cap Y = \emptyset \).

Note that \( M[v, s, b] \) \( r \)-represents \( \mathcal{A}_{v,s,b} \cup \mathcal{B}_{v,s,b} \), and therefore \( \mathcal{A}_{v,s,b} \cup \mathcal{B}_{v,s,b} \) contains a set that is disjoint from \( Y \), so does \( M[v, s, b] \). Thus, it is sufficient that we show that there exists \( \tilde{X} \in \mathcal{A}_{v,s,b} \cup \mathcal{B}_{v,s,b} \) such that \( \tilde{X} \cap Y = \emptyset \).

Since \( X \in \mathcal{S}_{v,s,b} \), there exists a good \((v, s, b)\)-path \( P \) such that \( \ell(P) = X \). Let \( u \) be the vertex on \( P \) that precedes \( v \), and let \( Q \) be the path obtained by removing \( v \) from \( P \).

Note that \( \ell(Q) \) \( X \setminus \{\ell(v)\} \). Thus, if \( c(u, v) = R \), then \( Q \) is a good \((u, s-1, b)\)-path and therefore \( X \setminus \{\ell(v)\} \in \mathcal{S}_{u,s-1,b} \) and otherwise \( Q \) is a good \((u, s-1, b-1)\)-path and therefore \( X \setminus \{\ell(v)\} \in \mathcal{S}_{u,s-1,b-1} \). First, let us assume that \( X \setminus \{\ell(v)\} \in \mathcal{S}_{u,s-1,b} \). By the inductive hypothesis, \( M[u, s-1, b] \) \( r \)-represents \( \mathcal{S}_{u,s-1,b} \), and therefore \( M[u, s-1, b] \) contains a set \( Z \) such that \( Z \cap (Y \cup \{\ell(v)\}) = \emptyset \). Thus, \( Z \cup \{\ell(v)\} \in \mathcal{A}_{v,s,b} \) and we conclude that the statement is correct. Now, let us assume that \( X \setminus \{\ell(v)\} \in \mathcal{S}_{u,s-1,b-1} \). By the inductive hypothesis, \( M[u, s-1, b-1] \) \( r \)-represents \( \mathcal{S}_{u,s-1,b-1} \), and therefore \( M[u, s-1, b-1] \) contains a set \( Z \) such that \( Z \cap (Y \cup \{\ell(v)\}) = \emptyset \). Thus, \( Z \cup \{\ell(v)\} \in \mathcal{B}_{v,s,b} \), and again we conclude that the statement is correct.
With these lemmas at hand, we are ready to prove Lemma 15.

**Proof.** By Observation 7 and Lemma 28, we first compute \( M \), ensuring that the condition in Lemma 28 is satisfied, in time \( O((\frac{1+\sqrt{2}}{2})^{r+\epsilon(r)} \cdot |E(G)| \log |E(G)|) \). Then, we determine that the input instance is a yes-instance if and only if there exist \( v \in V(G) \), \( s \in [r] \) and \( b \in [r] \) such that \( b \geq k \) and \( M[v, s, b] \neq \emptyset \). On the one hand, since for all \( v \in V(G) \), \( s \in [r] \) and \( b \in [r] \), \( M[v, s, b] \subseteq S_{v, s, b} \), it is clear that if we accept, the input instance is indeed a yes-instance. On the other hand, if the input instance is a yes-instance, then there exist \( v \in V(G) \), \( s \in [r] \) and \( b \in [r] \) such that \( b \geq k \) and \( S_{v, s, b} \neq \emptyset \). Then, since \( M[v, s, b] \) 0-represents \( S_{v, s, b} \), it holds that \( M[v, s, b] \neq \emptyset \), and therefore we accept. \( \Box \)

## C. Proofs of Section 5

### Proof of Theorem 23.

We first show the running time to construct the kernel.

**Proposition 29.** For each \( S \in \{A, B\} \), \( |C_S| = O(k^3) \) and \( C_S \) can be constructed in time \( O(|\Sigma|^2 \cdot n) + O(k^3 \cdot n) \).

**Proof.** By assumption \( |\text{rare}(S)| \leq 4k \). Additionally, for each \( i \), the ball \( B_b(i) \) has size at most \( 2k + 1 \). Finally, for each duo \( (i, i + 1) \) that is rare for \( S \), the set \( F(\mathcal{S}, i, i + 1) \) has at most \( (2k - 1)(2k + 1) \) duos. Therefore, \( |C_S| \leq 4k(2k + 1) + 4k(2k - 1)(2k + 1) = O(k^3) \).

Now let us analyze the time to construct \( C_S \). First, the construction of the sets \( \text{rare}(S) \) and \( \text{rare}(\mathcal{S}) \) takes time \( O(|\Sigma|^2 \cdot n) \), since we just need to count for each length-two string \( ab \in \Sigma \times \Sigma \), the number of times \( n(S, a, b) \) that \( ab \) occurs in \( S \) and the number of times \( n(S, a, b) \) that \( ab \) occurs in \( \mathcal{S} \). Now, for each position \( i \in \{1, \ldots, n - 1\} \), we add \((i, i + 1) \) to \( \text{rare}(S) \) if \( S[i]S[i + 1] = ab \) and \( n(S, a, b) \leq n(S, a, b) \). Analogously, we add \((i, i + 1) \) to \( \text{rare}(\mathcal{S}) \) if \( \mathcal{S}[i]\mathcal{S}[i + 1] = ab \) and \( n(\mathcal{S}, a, b) \leq n(S, a, b) \).

Now, the construction of the set \( \text{Roots}(S, i, i + 1) \) according to Algorithm 1 takes time \( O(k^2 \cdot n) \). Since \( \text{Roots}(S, i, i + 1) \leq 2k - 1 \), and by assumption \( |\text{rare}(S)| \leq 4k \), the construction of \( F(S, i, i + 1) \) also takes time \( O(k^2 \cdot n) \). Analogously, the construction of \( F(\mathcal{S}, i, i + 1) \) takes time \( O(k^2 \cdot n) \). Therefore, the construction of \( C_S \) takes time at most \( O(|\Sigma|^2 \cdot n) + O(k^3 \cdot n) \). \( \Box \)

**Theorem 23.** Given an instance \( I = (A, B, k) \) of MAX-DUO PSM, one can construct in time \( O(|\Sigma|^2 \cdot n + k^3 \cdot n) \) an instance \( I' = (A', B', k') \) of MAX-DUO PSM with \( |A'| \) and \( |B'| \) bounded by \( O(k^3) \) such that \( I \) is a yes-instance if and only if \( I' \) is a yes-instance.

**Proof.** First, if some map \( m \) of \( A \) into \( B \) preserves a block \( X \) of size \( k \), then \( (A, B, k) \) is a yes-instance for MAX-DUO PSM and we can output in \( O(1) \) time an equivalent instance of constant size. Note that this condition can be verified in time \( O(n) \) by solving the LONGEST COMMON SUBSTRING problem for \( A \) and \( B \).

Second, if \( \text{rare}(A) \geq 4k \) or \( \text{rare}(B) \geq 4k \), then \( (A, B, k) \) is a yes-instance for MAX-DUO PSM, and we can output in \( O(1) \) time an equivalent instance of constant size.

Now since no map preserves a block of size \( k \), and if both \( \text{rare}(A) < 4k \) and \( \text{rare}(B) < 4k \), then by Lemma 22, the pair \((C_A, C_B)\) constructed according to Equation 1 is complete for \((A, B, k)\). Additionally, by Proposition 29, \(|C_A| = |C_B| = O(k^3)\), and both \( C_A \) and \( C_B \) can be constructed in time \( O(|\Sigma|^2 \cdot n + k^3 \cdot n) \).

Since the complete pair \((C_A, C_B)\) constructed has size at most \( O(k^3) \), we can apply Theorem 17 to construct in time \( O(k^3) \) an instance \((A', B', k)\) for MAX-DUO PSM of size \( O(k^3) \) such that \((A', B', k)\) is a yes-instance if and only if \((A, B, k)\) is a yes-instance. Therefore, the overall time to construct \((A', B', k)\) is upper-bounded by \( O(|\Sigma|^2 \cdot n + k^3 \cdot n) \). \( \Box \)
Clique-Based Lower Bounds for Parsing Tree-Adjoining Grammars

Abstract

Tree-adjoining grammars are a generalization of context-free grammars that are well suited to model human languages and are thus popular in computational linguistics. In the tree-adjoining grammar recognition problem, given a grammar $\Gamma$ and a string $s$ of length $n$, the task is to decide whether $s$ can be obtained from $\Gamma$. Rajasekaran and Yooseph’s parser (JCSS’98) solves this problem in time $O(n^{2\omega})$, where $\omega < 2.373$ is the matrix multiplication exponent. The best algorithms avoiding fast matrix multiplication take time $O(n^6)$.

The first evidence for hardness was given by Satta (J. Comp. Linguist.’94): For a more general parsing problem, any algorithm that avoids fast matrix multiplication and is significantly faster than $O(|\Gamma|n^6)$ in the case of $|\Gamma| = \Theta(n^{12})$ would imply a breakthrough for Boolean matrix multiplication.

Following an approach by Abboud et al. (FOCS’15) for context-free grammar recognition, in this paper we resolve many of the disadvantages of the previous lower bound. We show that, even on constant-size grammars, any improvement on Rajasekaran and Yooseph’s parser would imply a breakthrough for the $k$-Clique problem. This establishes tree-adjoining grammar parsing as a practically relevant problem with the unusual running time of $n^{2\omega}$, up to lower order factors.

1 Introduction

Introduced in [14, 15], tree-adjoining grammars (TAGs) are a system to manipulate certain trees to arrive at strings, see Section 2 for a definition. TAGs are more powerful than context-free grammars, capturing various phenomena of human languages which require more formal power; in particular TAGs have an “extended domain of locality” as they allow “long-distance dependencies” [16]. These properties, and the fact that TAGs are efficiently parsable [29], make them highly desirable in the field of computer linguistics. This is illustrated by the large literature on variants of TAGs (see, e.g., [30, 21, 24, 9]), their formal language properties (see, e.g., [29, 16]), as well as practical applications (see, e.g., [25, 13, 26, 2]), including the XTAG project which developed a tree-adjoining grammar for the English language [10]. In fact, TAGs are so fundamental to computer linguistics that there is a biannual meeting called “International Workshop on Tree-Adjoining Grammars and Related Formalisms” [7], and they are part of the undergraduate curriculum (at least at Saarland University).
The prime algorithmic problem on TAGs is parsing (sometimes called recognition): Given a TAG $\Gamma$ and a string $s$ of length $n$, decide whether $\Gamma$ can generate $s$. The first TAG parsers ran in time $O(n^6)$ [29, 23], which was improved by Rajasekaran and Yooseph [20] to $O(n^{2.373})$, where $\omega < 2.373$ is the exponent of (Boolean) matrix multiplication.

A limited explanation for the complexity of TAG parsing was given by Satta [22], who designed a reduction from Boolean matrix multiplication to TAG parsing, showing that any TAG parser running faster than $O(|\Gamma|^n)$ on grammars of size $|\Gamma| = \Theta(12^n)$ yields a Boolean matrix multiplication algorithm running faster than $O(n^2)$. This result has several shortcomings: (1) It holds only for a more general parsing problem, where we need to determine for each substring of the given string $s$ whether it can be generated from $\Gamma$. (2) It gives a matching lower bound only in the unusual case of $|\Gamma| = \Theta(n^{12})$, so that it cannot exclude time, e.g., $O(|\Gamma|^2n^4)$. (3) It gives matching bounds only restricted to combinatorial algorithms, i.e., algorithms that avoid fast matrix multiplication\(^2\). Thus, so far there is no satisfying explanation of the complexity of TAG parsing.

1.1 Context-free grammars

The classic problem of parsing context-free grammars, with important applications in programming languages, was in a very similar situation as tree-adjoining grammar parsing until very recently. Parsers in time $O(n^3)$ were known since the 60s [8, 31, 17, 11]. In a breakthrough, Valiant [27] improved this to $O(n^2)$. Finally, a reduction from Boolean matrix multiplication due to Lee [18] showed a matching lower bound for combinatorial algorithms for a more general parsing problem in the case that the grammar size is $\Theta(n^k)$.

Abboud et al. [1] gave the first satisfying explanation for the complexity of context-free parsing, by designing a reduction from the classic $k$-Clique problem, which asks whether there are $k$ pairwise adjacent vertices in a given graph $G$. For this problem, for any fixed $k$ the trivial running time of $O(n^k)$ can be improved to $O(n^{k/3})$ for any $k$ divisible by 3 [19] (see [12] for the case of $k$ not divisible by 3). The fastest combinatorial algorithm runs in time $O(n^k / \log^k n)$ [28]. The $k$-Clique hypothesis states that both running times are essentially optimal, specifically that $k$-Clique has no $O(n^{(\omega/3-\varepsilon)k})$ algorithm and no combinatorial $O(n^{k+1-k})$ algorithm for any $k \geq 3, \varepsilon > 0$. The main result of Abboud et al. [1] is a reduction from the $k$-Clique problem to context-free grammar recognition on a specific, constant-size grammar $\Gamma$, showing that any $O(n^{k+\varepsilon})$ algorithm or any combinatorial $O(n^{3+\varepsilon})$ algorithm for context-free grammar recognition would break the $k$-Clique hypothesis, and thus improve decades-old algorithms. This matching conditional lower bound removes all disadvantages of Lee’s lower bound at the cost of introducing a hypothesis, see [1] for further discussions.

1.2 Our contribution

We extend the approach by Abboud et al. to the more complex setting of TAGs. Specifically, we design a reduction from the 6k-Clique problem to TAG recognition:

**Theorem.** There is a tree-adjoining grammar $\Gamma$ of constant size such that if we can decide in time $T(n)$ whether a given string of length $n$ can be generated from $\Gamma$, then 6k-Clique can be solved in time $O(T(n^{k+1} \log n))$, for any fixed $k \geq 1$. This reduction is combinatorial.

---

1 In most running time bounds we ignore the dependence on the grammar size, as we are mostly interested in constant-size grammars in this paper.

2 There is no agreed upon formal definition of combinatorial algorithms.
Via this reduction, any $O(n^{2\omega-\varepsilon})$ algorithm for TAG recognition would prove that 6k-Clique is in time $\tilde{O}(n^{(2\omega-\varepsilon)(k+1)} = O(n^{(ω/3-ε/9)6k})$, for sufficiently large $k$. Furthermore, any combinatorial $O(n^{6-\varepsilon})$ algorithm for TAG recognition would yield a combinatorial algorithm for 6k-Clique in time $\tilde{O}(n^{(6-\varepsilon)(k+1)}) = O(n^{(1-ε/9)6k})$, for sufficiently large $k$. As both implications would violate the 6k-Clique conjecture, we obtain tight conditional lower bounds for TAG recognition. As our result (1) works directly for TAG recognition instead of a more general parsing problem, (2) holds for constant size grammars, and (3) does not need the restriction to combinatorial algorithms, it overcomes all shortcomings of the previous lower bound based on Boolean matrix multiplication, at the cost of using the well-established k-Clique hypothesis, which has also been used in [1, 5, 6, 3, 4].

We thus establish TAG parsing as a practically relevant problem with the quite unusual running time of $n^{2\omega}$, up to lower order factors. This is surprising, as the authors are aware of only one other problem with a (conjectured or conditional) optimal running time of $n^{2\omega±o(1)}$, namely 6-Clique.

1.3 Techniques

The essential difference of tree-adjoining and context-free grammars is that the former can grow strings at four positions, see Figure 3a. Writing a vertex $v_1$ in one position of the string, and writing the neighborhoods of vertices $v_2, v_3, v_4$ at other positions in the string, a simple tree-adjoining grammar can test whether $v_1$ is adjacent to $v_2, v_3, v_4$. Extending this construction, for $k$-cliques $C_1, C_2, C_3, C_4$ we can test whether $C_1 \cup C_2, C_1 \cup C_3, C_1 \cup C_4$ form 2k-cliques. Using two permutations of this test, we ensure that $C_1 \cup C_2 \cup C_3 \cup C_4$ forms an almost-4k-clique, i.e., only the edges $C_3 \times C_4$ might be missing (in Figure 2b below this situation is depicted for cliques $C_2, C_3, C_1, C_6$ instead of $C_1, C_2, C_3, C_4$). Finally, we use that a 6k-clique can be decomposed into 3 almost-4k-cliques, see Figure 2a.

In the constructed string we essentially just enumerate 6 times all $k$-cliques of the given graph $G$, as well as their neighborhoods, with appropriate padding symbols (see Section 3). We try to make the constructed tree-adjoining grammar as easily accessible as possible by defining a certain programming language realized by these grammars, and phrasing our grammar in this language, which yields subroutines with an intuitive meaning (see Section 4).

2 Preliminaries on tree-adjoining grammars

In this section we define tree-adjoining grammars and give examples. Fix a set $T$ of terminals and a set $N$ of non-terminals. In the following, conceptually we partition the nodes of any tree into its leaves, the root, and the remaining inner nodes. An initial tree is a rooted tree where

- the root and each inner node is labeled with a non-terminal,
- each leaf is labeled with a terminal, and
- each inner node can be marked for adjunction.

See Figure 1a for an example; nodes marked for adjunction are annotated by a rectangle. An auxiliary tree is a rooted tree where

- the root and each inner node is labeled with a non-terminal,
- exactly one leaf, called the foot node, is labeled with the same non-terminal as the root,
- each remaining leaf is labeled with a terminal, and
- each inner node can be marked for adjunction.

---

3 For this and the next statement it suffices to set $k > 18/ε$. 

CPM 2017
(a) An initial tree (left) and an auxiliary tree (right); the internal nodes labeled $A$ and $B$ are marked for adjunction.

(b) Resulting tree after adjoining the auxiliary tree into the initial tree.

![Figure 1](image_url) The basic building blocks and operation of tree-adjoining grammars.

Initial trees are the starting points for derivations of the tree-adjoining grammar. These trees are then extended by repeatedly replacing nodes marked for adjunction by auxiliary trees. Formally, given an initial or auxiliary tree $t$ that contains at least one inner node $v$ marked for adjunction and given an auxiliary tree $a$ whose root $r$ has the same label as $v$, we can combine these trees with the following operation called adjunction, see Figure 1 for an example.

1. Replace $a$’s foot node by the subtree rooted at $v$.
2. Replace the node $v$ with the tree obtained from the last step, which is rooted at $r$.

Note that these steps make sense, since $r$ and $v$ have the same label. Note that adjunction does not change the number leaves labeled with a non-terminal symbol, i.e., an initial tree will stay an initial tree and an auxiliary tree will stay an auxiliary tree.

A tree-adjoining grammar is now defined as a tuple $\Gamma = (I, A, T, N)$ where

- $I$ is a finite set of initial trees and
- $A$ is a finite set of auxiliary trees,

using the same terminals $T$ and non-terminals $N$ as labels. The set $D$ of derived trees of $\Gamma$ consists of all trees that can be generated by starting with an initial tree in $I$ and repeatedly adjoining auxiliary trees in $A$. (Note that each derived tree is also an initial tree, but not necessarily in $I$.) Finally, a string $s$ over alphabet $T$ can be generated by $\Gamma$, if there is a derived tree $t$ in $D$ such that

- $t$ contains no nodes marked for adjunction and
- $s$ is obtained by concatenating the labels of the leaves of $t$ from left to right.

The language $L(\Gamma)$ is then the set of all strings that can be generated by $\Gamma$.

### 3 Encoding graphs

Given a graph $G = (V, E)$, we construct a string $GG_k(G)$ that encodes its $k$-cliques, over the terminal alphabet $T = \{0, 1, \$, #, |, $e, l_1, \ldots, l_6, r_1, \ldots, r_6\}$ of size 19. In the next section we then design a tree-adjoining grammar $\Gamma$ that generates $GG_k(G)$ if and only if $G$ contains a $6k$-clique. We assume that $V = |V|$, and we denote the binary representation of any $v \in V$ by $\pi$ and the neighborhood of $v$ by $N(v)$. For two strings $a$ and $b$, we use $a \circ b$ to denote their concatenation and $a^R$ to denote the reverse of $a$.

We start with node and list gadgets, encoding a vertex and its neighborhood, respectively:

$\text{NG}(v) := \$\pi\$ and $\text{LG}(v) := \bigcirc_{u \in N(v)} \text{NG}(u)$

$\bigcirc_{u \in N(v)} \$\pi\$ \$
(a) Each $C_i$ is a $k$-clique and there is an edge between two $k$-cliques of some highlighting style if the clique gadgets of that style ensure that these two cliques together form a $2k$-clique.

**Figure 2** Structure of our test for $6k$-cliques.

Note that $u$ and $v$ are adjacent iff $\text{NG}(u)$ is a substring of $\text{LG}(v)$.

Next, we build clique versions of these gadgets, that encode a $k$-clique $C$ and its neighborhood, respectively:

$$\text{CNG}(C) := \bigcup_{v \in C} (\# \text{NG}(v) \#)^k \quad \text{and} \quad \text{CLG}(C) := \left( \bigcup_{v \in C} \# \text{LG}(v) \# \right)^k$$

Note that two $k$-cliques $C$ and $C'$ form a $2k$-clique if and only if $\text{CNG}(C)$ is a subsequence of $\text{CLG}(C')$, since every pair of a vertex in $C$ and a vertex in $C'$ is tested for adjacency. We will later show how to implement this test for forming a $2k$-clique with a tree-adjoining grammar.

Conceptually, we split any $6k$-clique into six $k$-cliques. Thus, let $C_k$ be the set of all $k$-cliques in $G$. Our final encoding of the graph is:

$$\text{GG}_k(G) := \bigcup_{C \in C_k} \begin{cases} \text{CNG}(C) \# \text{CLG}(C)^R & l_1 r_1 \text{CLG}(C) \# \text{CLG}(C)^R \\ \text{CNG}(C) \# \text{CLG}(C)^R & l_2 r_2 \text{CLG}(C) \# \text{CLG}(C)^R \\ \text{CNG}(C) \# \text{CLG}(C)^R & l_3 r_3 \text{CLG}(C) \# \text{CLG}(C)^R \\ \text{CLG}(C) \# \text{CLG}(C)^R & l_4 r_4 \text{CNG}(C) \# \text{CLG}(C)^R \\ \text{CLG}(C) \# \text{CLG}(C)^R & l_5 r_5 \text{CNG}(C) \# \text{CLG}(C)^R \\ \text{CLG}(C) \# \text{CLG}(C)^R & l_6 r_6 \text{CNG}(C) \# \text{CLG}(C)^R \end{cases}$$

As we will show, there is a tree-adjoining grammar of constant size that generates the string $\text{GG}_k(G)$ iff $G$ contains a $6k$-clique. The structure of this test is depicted in Figure 2. The clique-gadgets of the same highlighting style together allow us to test for an almost-$4k$-clique, as it is depicted in Figure 2a. The two gadgets of the same highlighting style then test for two claws of cliques, as depicted in Figure 2b.

As the graph has $n$ nodes, for any node $u$ the node and list gadgets $\text{NG}(u), \text{LG}(u)$ have a length of $O(n \log n)$, and for a $k$-clique $C$ the clique neighborhood gadgets $\text{CNG}(C), \text{CLG}(C)$ thus have a length of $O(k^2 n \log n)$. As our encoding of the graph consists of $O(n^k)$ clique neighborhood gadgets, the resulting string length is $O(k^2 n^{k+1} \log n) = O(n^{k+1} \log n)$. It is
easy to see that it is also possible to construct all gadgets and in particular the encoding of a graph in linear time with respect to their length.

4 Programming with trees

It remains to design a clique-detecting tree-adjoining grammar. To make our reduction more accessible, we will think of tree-adjoining grammars as a certain programming language. In the end, we will then present a “program” that generates (a suitable superset of) the set all strings that represent a graph containing a \( k \)-clique. We start by defining programs.

A normal tree with input and output is an auxiliary tree where:

- the root is labeled with \( N_{In} \),
- exactly one node is marked for adjunction, and
- this node lies on the path from the root to the foot node and is labeled \( N_{Out} \).

See Figure 3a for an illustration. The special structure of a normal tree allows us to split its nodes into four categories (excluding the path from \( N \)'s root to its foot node): subtrees of left children of the path from \( N \)'s root to \( N_{Out} \), subtrees of left children of the path from \( N_{Out} \) to \( N \)'s foot node, subtrees of right children of the path from \( N_{Out} \) to \( N \)'s foot node, and the remaining nodes (i.e., subtrees of right children of the path from \( N \)'s root to \( N_{Out} \)). The concatenation of all terminal symbols in \( N \)'s leaves from left to right can then be split into four parts \( n_1, n_2, n_3, n_4 \) where each part contains symbols from exactly one category. We say that the normal tree \( N \) generates the tuple \( (n_1, n_2, n_3, n_4) \).

Lemma 4.1. Given normal trees with input \( N_{In} \) and output \( N_{Out} \) and \( M \) with input \( M_{In} = N_{Out} \), output \( M_{Out} \), the derived tree \( N \cdot M \) obtained by adjoining \( M \) into \( N \) is a normal tree with input \( N_{In} \) and output \( M_{Out} \). Further, if \( N \) and \( M \) generate the tuples \( (n_1, n_2, n_3, n_4) \) and \( (m_1, m_2, m_3, m_4) \), then \( N \cdot M \) generates the tuple \( (n_1 \circ m_1, m_2 \circ n_2, n_3 \circ m_3, m_4 \circ n_4) \).

Proof. See Figure 3.

We now define a program \( P \) with input \( P_{In} \) and output \( P_{Out} \) as a set of normal trees that contains a tree with input \( P_{In} \) and a tree with output \( P_{Out} \). Note that all trees derived by starting with a tree in \( P \) and repeatedly adjoining trees from \( P \) are normal, by Lemma 4.1. An execution of the program \( P \) is a derived tree of \( P \) with input \( P_{In} \) and output \( P_{Out} \). Further, the set computed by \( P \), denoted by \( L(P) \), is the set of all tuples generated by \( P \)'s executions.

We will later use programs as subroutines of tree-adjoining grammars. Let \( N(P) \) be the set of non-terminals of \( P \). Formally, we say that \( P \) is a subroutine of a grammar \( \Gamma \) if
the set of trees $P$ is a subset of the auxiliary trees of $\Gamma$, and

- no remaining auxiliary tree of $\Gamma$ has a root label in $N(P) \setminus \{P_{Out}\}$.

These restrictions ensure that any “call” to the program $P$ terminates at $P_{Out}$. Indeed, consider any sequence of adjuncions in $\Gamma$ ending in a tree without nodes marked for adjunction. If this sequence contains an adjunction of a node labeled $P_{In}$, meaning that program $P$ is called, then this adjunction must be followed by an execution of $P$, i.e., it must generate a derived tree of $P$ with output $P_{Out}$. Indeed, any derived tree of $P$ is normal and thus contains exactly one node marked for adjunction. To get rid of this node, we have to adjoin some auxiliary tree, but the remaining auxiliary trees can only adjoin to $P_{Out}$. We will frequently make use of this observation that ensures coherence of programs.

We now show how to perform two programs sequentially one after another. To avoid interference, we ensure that the two programs have disjoint non-terminals, except for their input and output. In particular, we will model two sequential calls to the same program by creating two copies of the program.

**Lemma 4.2 (Combining programs).** For programs $P$ and $Q$, let $Q'$ denote the program obtained from $Q$ by replacing each non-terminal by a fresh copy, ensuring that $P$ and $Q'$ have disjoint non-terminals. Further, let $Q''$ denote the program obtained from $Q'$ by replacing $Q'_{In}$ by $P_{Out}$. Then $P \cdot Q := P \cup Q''$ is a program computing the set

$$L(P \cdot Q) := \{(a \circ a', b' \circ b, c \circ c', d' \circ d) \mid (a, b, c, d) \in L(P), (a', b', c', d') \in L(Q)\}.$$  

**Proof.** As every execution of $P$ and $Q''$ is a normal tree, the claim follows from Lemma 4.1.

We can think of $\cdot$ as an operator on programs; the above lemma shows that it is associative.

## 4.1 Basic programs

We now present some easy programs that will later be used as subroutines.

### 4.1.1 Writing characters

We start by demonstrating a program that writes exactly one character to each of the four positions. Formally, given a 4-tuple of characters $(a, b, c, d)$, let the program $W(a, b, c, d)$ be defined by the following auxiliary tree:

```
      W(a, b, c, d)_{In}
       /   \
      a     d
     / \   / \
    b   W(a, b, c, d)_{Out}
       /   \
      c    W(a, b, c, d)_{In}
```

Clearly, this tree is normal with input $W(a, b, c, d)_{In}$ and output $W(a, b, c, d)_{Out}$, so that $W(a, b, c, d)$ is a program. The tree itself is an execution of the program, and it is the only execution. Thus, this program computes the set $L(W(a, b, c, d)) = \{(a, b, c, d)\}$. We write $W(a)$ to denote the program $W(a, a, a, a)$.
4.1.2 Testing equality

We give a program that tests equality of four strings, by writing the same arbitrary string to all four positions. Formally, for any terminal alphabet $\Sigma$, let the program $Eq(\Sigma)$ be defined by the following set of $|\Sigma| + 1$ auxiliary trees:

![Diagram of Eq(\Sigma) program]

A simple induction shows that $L(Eq(\Sigma)) = \{(v, v^R, v, v^R) \mid v \in \Sigma^*\}.$

4.1.3 Writing anything

We will need to write appropriate strings surrounding some carefully constructed substrings. As it turns out, being able to write anything will be sufficient; this is achieved by the following program. Given an alphabet $\Sigma$, let the program $A(\Sigma)$ be defined by the following set of $4|\Sigma| + 1$ trees:

![Diagram of A(\Sigma) program]

As this program allows writing anything, it is easy to see that $A(\Sigma)$ computes the set $(\Sigma^*)^4$.

4.2 Detecting Cliques

With the help of the above programs, we now design programs that detect a $6k$-clique.

4.2.1 Detecting claws

Our next program can detect whether four nodes form a claw graph.

$NC := W(#) \cdot A(\{0, 1, \$\}) \cdot W(\$) \cdot Eq(\{0, 1\}) \cdot W(\$) \cdot A(\{0, 1, \$\}) \cdot W(\#)$

**Lemma 4.3.** For any nodes $v_1, v_2, v_3, v_4$, the program $NC$ generates the tuple

$(a, b, c, d) := (# NG(v_1) \#, # LG(v_2)^R \#, # LG(v_3) \#, # LG(v_4)^R \#)$

and any of its cyclic rotations (i.e., $(b, c, d, a)$, $(c, d, a, b)$, and $(d, a, b, c)$) if and only if $v_1$ is adjacent to each one of $v_2, v_3,$ and $v_4$.

**Proof.** By Lemma 4.2 and the properties of basic programs, we see that $NC$ computes all tuples of the form

$(# \alpha_1 \$ v \$ \alpha_2 \#, # \alpha_3 \$ v^R \$ \alpha_4 \#, # \alpha_5 \$ v \$ \alpha_6 \#, # \alpha_7 \$ v^R \$ \alpha_8 \#)$
where \( v \in \{0, 1\}^* \) and \( \alpha_1, \ldots, \alpha_8 \in \{0, 1, \$\}^* \). From the construction of node and list gadgets we see that all tuples \((\#\text{NG}(v_1)\#, \#\text{LG}(v_2)^R\#\#, \#\text{LG}(v_3)\#, \#\text{LG}(v_4)^R\#)\) are of this form.

For the other direction, for any generated tuple \((a, b, c, d)\), where \( a \) is \( \$ v \$ \), it holds that \( v \$ \) or its reverse is a substring of \( b, c, \) and \( d \). Hence, \( \text{NG}(v_1) \) is a substring of \( \text{LG}(v_2), \text{LG}(v_3), \) and \( \text{LG}(v_4) \). This implies that \( v_1 \) is adjacent to \( v_2, v_3, \) and \( v_4 \).

\[\text{Lemma 4.4.}\] For any \( k \)-cliques \( C_1, C_2, C_3, C_4 \) in \( G \), the program \( CC \) generates the tuple \((\text{NG}(C_1), \text{CLG}(C_2)^R, \text{CLG}(C_3), \text{CLG}(C_4)^R)\) and all of its cyclic rotations (i.e., \((b, c, d, a), (c, d, a, b), \) and \((d, a, b, c)\)) if and only if \( C_1 \cup C_2, C_1 \cup C_3, \) and \( C_1 \cup C_4 \) each form a 2k-clique in \( G \).

\[\text{Proof.}\] For any nodes \( v_i \), with \( i \in [4], j \in [m], m \geq 1 \), set

\[n_i := \bigcirc_{j \in [m]} \# \text{NG}(v_i^j)\# \quad \text{and} \quad \ell_i := \bigcirc_{j \in [m]} \# \text{LG}(v_i^j)\#.
\]

As program \( CC \) can perform any number of calls to \( NC \), and by Lemma 4.3, program \( CC \) generates the tuple \((n_1, \ell_2, \ell_3, \ell_4)\) if and only if \( v_i^j \) is adjacent to \( v_i^j, v_i^j, \) and \( v_i^j \) for all \( j \).

Observe that for any \( k \)-cliques \( C_1 = \{v_1, \ldots, v_k\}, C_2 = \{u_1, \ldots, u_k\} \), both \( \text{CNG}(C) \) and \( \text{CLG}(C) \) can be split into \( k^2 \) blocks by splitting between two consecutive \#-characters:

\[
\text{CNG}(C_1) = \# \text{NG}(v_1) \# \# \# \# \text{NG}(v_1) \# \cdots \# \# \# \# \text{NG}(v_1) \# \# \# \# \text{NG}(v_2) \# \cdots \\
\text{CLG}(C_2) = \# \text{LG}(u_1) \# \# \# \# \text{LG}(u_1) \# \cdots \# \# \# \# \text{LG}(u_k) \# \# \# \# \text{LG}(u_1) \# \cdots
\]

This layout is chosen so that each node \( v_i \) in \( C_1 \) is paired up with each node \( u_j \) in \( C_2 \) exactly once. The claim follows from these two insights.

\[\text{Lemma 4.2.}\] Detecting almost-4k-cliques

We now use \( CC \) twice to test for two claws, thus detecting “almost-4k-cliques”, as depicted in Figure 2b:

\[C := CC \cdot W(\$) \cdot CC.
\]

Lemmas 4.4 and 4.2 directly imply the following, see Figure 2b.

---

4 Actually, we already know how many calls to \( NC \) we want to perform, namely \( k^2 \). However, encoding this number into the grammar would result in a grammar size depending on \( k \), which we want to avoid.
Lemma 4.5. For any $k$-cliques $C_a, C_b, C_c, C_d$ the program $C$ generates the tuple

\[(\text{CNG}(C_a) \not\subseteq \text{CLG}(C_a)^R, \text{CLG}(C_b) \not\subseteq \text{CLG}(C_b)^R, \text{CLG}(C_c) \not\subseteq \text{CLG}(C_c)^R, \text{CLG}(C_d) \not\subseteq \text{CLG}(C_d)^R)\]

if and only if $C_a \cup C_b \cup C_d$ and $C_a \cup C_c \cup C_d$ both form a $3k$-clique. A similar statement holds if we pick any two other positions in the tuple for the CNG$(\cdot)$ gadgets.

4.2.4 Detecting 6k-cliques

As in Figure 2a, we now want to test for three almost-4k-cliques to detect a 6k-clique. Recall that $T = \{0, 1, $, $, \#, $, $, $, e, l_1, \ldots, l_6, r_1, \ldots, r_6\}$ is the terminal alphabet that we constructed our strings over. The following programs will generate the highlighted groups in Figure 2a:

\[
P(1, 3, 4, 6) := A(T) \cdot W() \cdot C \cdot W(l_1, r_3, l_4, r_6)
\]

\[
P(1, 2, 5, 6) := W(r_1, l_2, r_5, l_6) \cdot C \cdot W() \cdot A(T),
\]

\[
P(2, 3, 4, 5) := W(r_2, l_3, r_4, l_5) \cdot C \cdot W() \cdot A(T),
\]

We now deviate from our notion of normal trees by explicitly not marking $P(1, 2, 5, 6)_{Out}$ and $P(2, 3, 4, 5)_{Out}$ for adjunction. Our final tree-adjoining grammar $\Gamma$ consists of the following initial and auxiliary trees (as well as all auxiliary trees used by its subroutines):

\[
S \quad P(1, 3, 4, 6)_{I_{ab}} \quad P(1, 3, 4, 6)_{O_{ab}} \quad P(1, 2, 5, 6)_{I_{ab}} \quad P(2, 3, 4, 5)_{I_{ab}} \quad P(2, 3, 4, 5)_{O_{ab}}
\]

Note that the latter tree is the only one in $\Gamma$ that has more than one node marked for adjunction, so it needs special treatment.

Lemma 4.6. For any graph $G$, the grammar $\Gamma$ generates the encoding $\text{GG}_k(G)$ if and only if $G$ contains a 6k-clique. Moreover, $\Gamma$ has constant size (independent of $k$).

\[\textbf{Proof.}\] First, assume that $\Gamma$ can generate $\text{GG}_k(G)$. Then there is a derived tree whose leaves, if read from left to right, yield $\text{GG}_k(G)$. All derivations of $\Gamma$ start with the single initial tree, and then adjoin an execution of the program $P(1,3,4,6)$ into it. (As $P(1,3,4,6)$ is a subroutine, only a full execution can be adjoined.) This execution generates some tuple of strings $(x_1, x_2, x_3, x_4)$ and leaves exactly the node labeled $P(1,3,4,6)_{Out}$ as the sole node marked for adjunction. Therefore, in the next step the auxiliary tree rooted with that node will be adjoined, which in turn leaves exactly the nodes $P(1,2,5,6)_{I_{ab}}$ and $P(2,3,4,5)_{I_{ab}}$ as nodes marked for adjunction. Again, these are input nodes of subroutines, therefore at both nodes one (complete) execution of the corresponding programs must be adjoined. The program execution of program $P(1,2,5,6)$ generates a tuple of strings $(y_1, y_2, y_3, y_4)$, and the execution of $P(2,3,4,5)$ generates $(x_1, x_2, x_3, x_4)$. The grammar $\Gamma$ ensures that these tuples will be placed in the order $(x_1, y_1, x_2, y_2, x_3, y_3, x_4, y_4, x_5, y_5, x_6, y_6)$, see Figure 4 for a visualization. At this point, no more adjunctions are possible, since we explicitly forced $P(1,2,5,6)_{Out}$ and $P(2,3,4,5)_{Out}$ not to be marked for adjunction. (Also
Consider the strings $x_1$ and $y_1$. By the definitions of $P(1,3,4,6)$ and $P(1,2,5,6)$, and Lemma 4.2, we know that $x_1$ must end with the terminal symbol $l_1$ and that $y_1$ must start with the symbol $r_1$. Whenever $l_1 r_1$ occurs in $GG_k(G)$, it does so in the string

$$[ \text{CNG}(C_1) \text{ CLG}(C_1) R ] \, l_1 \, \text{CLG}(C_1) \text{ CLG}(C_1) R ],$$

for some $k$-clique $C_1$. Since $x_1 \circ y_1$ is a substring of $GG_k(G)$, and the program $C$ cannot produce a $|-$terminal, but the $W(|)$ part of $P(\cdot, \cdot, \cdot, \cdot)$ will always write such a $|-$character, $x_1$ must have $| \text{CNG}(C_1) \text{ CLG}(C_1) R ] \, l_1$ as a suffix and $y_1$ must have $r_1 \text{ CLG}(C_1) \text{ CLG}(C_1) R |$ as a prefix. This also means that the program $C$ must generate the string between $|$ and $l_1$ in $x_1$, and between $|$ and $r_1$ in $y_1$.

Similar statements hold for the other ten strings. In total we obtain that the program $C$ generates the following tuples for some $k$-cliques $C_1, \ldots, C_6$:

- $t_1 := (\text{CNG}(C_1) \text{ CLG}(C_1) R, \text{CLG}(C_2) \text{ CLG}(C_2) R, \text{CLG}(C_3) \text{ CLG}(C_3) R) \text{ in } P(1,3,4,6)$,
- $t_2 := (\text{CNG}(C_1) \text{ CLG}(C_1) R, \text{CNG}(C_2) \text{ CLG}(C_2) R, \text{CLG}(C_3) \text{ CLG}(C_3) R) \text{ in } P(1,2,5,6)$, and
- $t_3 := (\text{CLG}(C_2) \text{ CLG}(C_2) R, \text{CNG}(C_3) \text{ CLG}(C_3) R, \text{CLG}(C_4) \text{ CLG}(C_4) R) \text{ in } P(2,3,4,5)$.

By Lemma 4.5, this implies that all $C_1 \cup \ldots \cup C_6$ form a $2k$-clique and thus $C_1 \cup \ldots \cup C_6$ forms a $6k$-clique (see Figure 2a to check that all pairs are covered).

For the other direction, consider a graph $G$ that contains a $6k$-clique $C^*$. Then we can split $C^*$ into 6 vertex-disjoint $k$-cliques $C_1, \ldots, C_6$. Further we know that every three of these six $k$-cliques together form a $3k$-clique. Thus, the program $C$ generates the tuples $t_1, t_2, t_3$ as above. We can then use the three programs $P(\cdot, \cdot, \cdot, \cdot)$ to generate such tuples surrounded with symbols $|, \, l_1, \text{ and } r_1$ at appropriate positions. Adding the surrounding strings by $A(T)$ and following the global structure of $\Gamma$ generates the encoding $GG_k(G)$. 

**Figure 4** Global structure of a parsing of $GG_k(G)$ by $\Gamma$. (Clique gadgets are abbreviated.)
To see that $\Gamma$ is of constant size, note that we only use constantly many programs. Thus using a new set of terminal symbols for every instance of a program will still yield a constant total number of non-terminal symbols. Further, we only use 19 terminal symbols.

The above lemma and the bound $|GG_k(G)| = O(n^{k+1} \log n)$ imply the main theorem.

Communication and Streaming Complexity of Approximate Pattern Matching

Tatiana Starikovskaya

tat.starikovskaya@gmail.com

Abstract

We consider the approximate pattern matching problem. Given a text $T$ of length $2n$ and a pattern $P$ of length $n$, the task is to decide for each prefix $T[1,j]$ of $T$ if it ends with a string that is at the edit distance at most $k$ from $P$. If this is the case, we must output the edit distance and the corresponding edit operations. We first look at the communication complexity of the problem. We show the following:

- If Alice and Bob both share the pattern and Alice holds the first half of the text and Bob the second half, then the deterministic one-way communication complexity of the problem is $\Theta(k \log n)$.
- If Alice holds the first half of the text, Bob the second half of the text, and Charlie the pattern, then there is a deterministic one-way communication protocol that uses $O(k\sqrt{n} \log n)$ bits.

We then develop the first sublinear-space streaming algorithm for the problem. There exists a streaming algorithm that solves the problem in $O(k^2 \sqrt{n} \log^6 n)$ space. The worst-case time complexity of the algorithm $O((k^2 \sqrt{n} + k^{13}) \cdot \log^4 n)$ per arrival. The algorithm is randomised with error probability at most $1/poly(n)$.

1 Introduction

In this work we study the famous approximate pattern matching problem. Recall that the edit distance between two strings $S_1, S_2$ is the minimum number of insertions, deletions, and substitutions required to transform $S_1$ to $S_2$. Assume we are given a pattern $P$ and a text $T$. We say that a substring $S$ of $T$ is a $k$-mismatch occurrence of $P$ if the edit distance between $S$ and $P$ is at most $k$. In the approximate pattern matching problem we must find all prefixes $T[1,j]$ of $T$ that end with a $k$-mismatch occurrence of $P$. The problem has numerous applications in bioinformatics, signal processing, text retrieval, and has received a lot of attention in the literature.

1.1 Our results

We first study the communication complexity of the problem, namely, we consider the following setting. Let $T$ be a text of length $2n$ and $P$ be a pattern of length $n$. Let Alice hold the information about the first half of the text, and let Bob hold the information about the second half of the text. Alice sends Bob a message, and Bob’s task is to find all prefixes $T[1,j]$ that end with a $k$-mismatch occurrence of $P$ and the edit operations that transform the occurrence into $P$ using only Alice’s message and his half of the text. The minimal size of
Alice's message that allows Bob to complete the task is called the communication complexity of the problem.

It is not hard to see that if both Bob and Alice have access to the pattern, the communication complexity is $\Theta(k \log n)$. Indeed, from the information theoretic lower bound it follows that Alice has to send at least $k \log n$ bits. On the other hand we can consider the following (deterministic) protocol. Alice first finds the smallest $i$ such that the edit distance between $T[i,n]$ and some prefix $P[1,j]$ of the pattern is at most $k$, and then sends the edit operations and $j$ to Bob. Bob uses the message from Alice to restore $T[i,n]$. He then knows both $T[i,2n]$ and $P$ and therefore can compute all outputs. (Note that the edit distance between $P$ and any substring of $T$ that starts in $[1,i]$ and ends in $[n+1,2n]$ is at least $k$, and therefore Bob does not need any information about $T[1,i]$). However, the situation is different when only the third party, Charlie, knows the pattern, as in this case Alice can no longer use the pattern to encode her half of the text. We show the following theorem.

**Theorem 1.** When both $P$ and $T$ are binary, the one-way deterministic communication complexity of the approximate pattern matching problem for three parties is $O(k \sqrt{n \log n})$.

The main idea of the proof is that if $k$-mismatch occurrences of the pattern in the text are rare, Alice can send them all to Bob. If on the other hand there are many $k$-mismatch occurrences of the pattern, two of them will be located close to each other and therefore the underlying text will be weakly periodic, which will allow to encode it in small space.

Our motivation to study the communication complexity of the problem is twofold. First, it can be viewed as a generalisation of the document exchange problem, where we have two parties Alice and Bob, Alice holds one string and Bob holds the other string, and Bob’s task is to decide the edit distance between their strings using the message Alice sends to him and his half of the text. If the distance is at most $k$, Bob must output the edit operations that transform his string into Alice’s string. Otherwise, he may simply say that the distance is too large. In the paper we will refer to Alice’s message as document exchange sketch. The problem has been studied both in deterministic and randomised settings [1, 4, 3, 8, 11, 15]. The protocol shown by Orlitsky in 1991 [15] has optimal complexity $\Theta(k \log n)$ and is deterministic. However, Bob needs $n^{\mathcal{O}(k)}$ time to compute the distance. Recently, Belazzougui showed a new deterministic protocol [1]. It has complexity $O(k^2 + k \log^2 n)$ and much lower computation time of $n \cdot \text{poly}(\log n)$. The best randomised protocol is due to [2] and has $O(k \cdot (\log^2 k + \log n))$ complexity and $n \cdot \text{poly}(\log n)$ computation time.

The second reason to study the communication complexity of the problem is its relation to streaming algorithms. Let us first remind the setting. Consider a pattern $P$ of length $n$ and a text $T$ of length $2n$ arriving as a stream, one symbol at a time. When a new symbol arrives we must decide if the current text ends with a $k$-mismatch occurrence of $P$ and if so output the edit operations that transform the occurrence into $P$. We assume the standard RAM model of computation. The time complexity is defined in the usual way, and the space complexity is defined as all the space used by the algorithm. In particular, if we store a copy of the pattern or of the text we must account for it. It is well-known that a communication complexity lower bound implies a similar space lower bound for a streaming algorithm. However, upper bounds provide some insight as well. Imagine that the algorithm processes the stream in non-overlapping blocks, then it needs an efficient way to encode the edit distances in each of the blocks, and one possible approach is to use the message that Alice sends to Bob in the communication complexity protocol. We will use this idea to show the first sublinear-space streaming algorithm for the problem.
Theorem 2. Assume that both $P$ and $T$ are binary and that $k < n^{1/c}$ for a sufficiently large constant $c > 0$. There is a streaming algorithm that solves the approximate pattern matching problem in $O(k^8 \sqrt{n} \log^6 n)$ space and $O((k^2 \sqrt{n} + k^{13}) \cdot \log^4 n)$ worst-case time per symbol. The algorithm is correct with probability $1 - 1/poly(n)$.

The main advance has become possible due to the result of Belazzougui and Zhang [2], who showed a sketch that can be used to compute the exact value of the edit distance between two strings if it is at most $k$. Our algorithm maintains such sketches for $O(\sqrt{n})$ suffixes of the text. To compute the edit distance between the pattern and the text the algorithm divides the pattern into two parts, a short prefix and a suffix aligned with one of the sketched suffixes of the text. The edit distance between the short prefix and the text is computed beforehand using dynamic programming and stored very compactly using the communication complexity approach. The edit distance between the suffix and the text is computed with the help of the sketches. We note that the requirement on the text length is not restrictive. Indeed, if the text’s length is larger than $2n$, then one can split it into blocks of length $2(n + k)$ which overlap by $n + k$ symbols (the last block can be shorter) and run the algorithm of Theorem 2 independently for each of the blocks. For each $k$-mismatch occurrence of $P$ there is a block containing it and therefore the algorithm is correct. The complexity of the algorithm and the error probability do not change.

As we have already mentioned the problem has been extensively studied in the literature. For a survey of previous solutions see [14]. The solutions can be roughly classified into four main types: dynamic programming algorithms, automata-based algorithms, filtering algorithms, and bit-parallelism. To the best of author’s knowledge, all previously known solutions require at least $\Omega(n/\log n)$ space, and thus our result exhibits a remarkable improvement in space complexity. On the other hand, the running time of our algorithm is rather large. This is because the nature of the sketches is very complex and we have to maintain them independently. We give further details in Sections 3 and 4.

1.2 Related work

Lower bounds. In this work we focus on computing small edit distances between a pattern and a stream. If however we were interested in computing all edit distances, we would have to spend at least $n^{1-\varepsilon}$ amortised time per output for any constant $\varepsilon > 0$ unless the strong Exponential Time Hypothesis is false. (The original bound was given for computing the edit distance between two strings, and our problem is harder.) The best unconditional time lower bound was shown by Clifford et al. [6] who considered the problem in the cell-probe model, where the time complexity of algorithm is measured as the number of cells that must be accessed to compute the output. This model is particularly strong and any lower bounds that hold in it hold in the RAM model as well. Clifford et al. showed that the expected amortised time of any randomised algorithm that solves the edit distance problem is $\Omega(\sqrt{\log n}/(\log \log n)^{3/2})$ per output.

Approximate pattern matching in a stream. Another formalisation of approximate pattern matching is the $k$-mismatch problem, where one must find all substrings of the text such that the Hamming distance between them and the pattern is at most $k$. The first streaming algorithm for this problem was given in [16]. It used $O(k^3 \log^7 n/\log \log n)$ space and $O(k^2 \log^5 n/\log \log n)$ time per arriving symbol. In [5] this result was improved in terms of the dependency on $k$ to $O(k^2 \log^{1+\varepsilon} n/\log \log n)$ space and $O(\sqrt{k} \log k + \log^4 n)$ time per arriving symbol. Finally, in [7] the authors studied communication and streaming complexities of computing approximate values of all Hamming distances between the pattern and the text.
2 Communication complexity

In this section we show Theorem 1. Recall that Alice holds the first half of the text, Bob the second half of the text, and only Charlie holds the pattern. Bob must find all prefixes $T[1,j]$ of $T$ that end with a $k$-mismatch occurrence of $P$ and output the edit operations that convert the occurrence into $P$.

2.1 Periodicity under edit distance

We start by introducing a notion of approximate period for the edit distance. The idea is that two close $k$-mismatch occurrences of the pattern imply weak periodicity of the text. We will use this property of the text to encode it in small space.

Definition 3. The $\alpha$-period of a string $S$ is a minimal integer $\ell > \alpha$ such that the edit distance between some prefix of $S$ and $S[\ell + 1, n]$ is at most $\alpha$.

Example 4. The 1-period of a string $S = bbaabb$ is 3. This is because $S[3,6] = aabb$ cannot be transformed into a prefix of $S$ using just one edit operation, while the edit distance between $S[4,6] = abb$ and $S[1,2]$ is exactly one.

The condition $\ell > \alpha$ is essential as any suffix $S[\ell + 1, n]$ can be transformed into $S$ by $\ell$ insertions. We now show that the $\alpha$-period can be used to encode the pattern in an efficient way similar to the way the period of a string can be used to encode it.

Lemma 5. If the $4k$-period of a string $S$ of length $n$ is $\rho > 4k$, then $S$ can be encoded in $O(\rho + k \log n)$ bits.

Proof. The encoding will occupy $O(\rho + k \log n)$ bits and contain the prefix and the suffix of $S$ of length $\rho$ (both taking $O(\rho)$ bits to store), and the at most $4k$ edit operations that transform a prefix $S'$ of $S$ into $S[\rho + 1, n]$. The information about the edit operations will include the type of the operation (insertion, deletion, substitution), the position, and the symbol itself.

We now show that the encoding is lossless. Consider the first $\rho$ symbols of $S'$. Let $i_1 \leq 4k$ be the number of these symbols that must be deleted. It follows that the remaining $\rho - i_1$ symbols of $S'$ must be aligned against the symbols of $S[\rho + 1, n]$. Therefore, using the encoding, we can restore (at least) the first $\rho - i_1$ symbols of $S[\rho + 1, n]$ and consequently $S'[1, 2\rho - i_1]$. (Recall that insertions and replacements are stored in the encoding explicitly.)

We now show that the encoding is lossless. Consider the first $\rho$ symbols of $S'$. Let $i_1 \leq 4k$ be the number of these symbols that must be deleted. It follows that the remaining $\rho - i_1$ symbols of $S'$ must be aligned against the symbols of $S[\rho + 1, n]$. Therefore, using the encoding, we can restore (at least) the first $\rho - i_1$ symbols of $S[\rho + 1, n]$ and consequently $S'[1, 2\rho - i_1]$. (Recall that insertions and replacements are stored in the encoding explicitly.)

We now show that the encoding is lossless. Consider the first $\rho$ symbols of $S'$. Let $i_1 \leq 4k$ be the number of these symbols that must be deleted. It follows that the remaining $\rho - i_1$ symbols of $S'$ must be aligned against the symbols of $S[\rho + 1, n]$. We now show that the encoding is lossless. Consider the first $\rho$ symbols of $S'$. Let $i_1 \leq 4k$ be the number of these symbols that must be deleted. It follows that the remaining $\rho - i_1$ symbols of $S'$ must be aligned against the symbols of $S[\rho + 1, n]$. Therefore, using the encoding, we can restore (at least) the first $\rho - i_1$ symbols of $S[\rho + 1, n]$ and consequently $S'[1, 2\rho - i_1]$. (Recall that insertions and replacements are stored in the encoding explicitly.)

We now show that the encoding is lossless. Consider the first $\rho$ symbols of $S'$. Let $i_1 \leq 4k$ be the number of these symbols that must be deleted. It follows that the remaining $\rho - i_1$ symbols of $S'$ must be aligned against the symbols of $S[\rho + 1, n]$. Therefore, using the encoding, we can restore (at least) the first $\rho - i_1$ symbols of $S[\rho + 1, n]$ and consequently $S'[1, 2\rho - i_1]$. (Recall that insertions and replacements are stored in the encoding explicitly.)

We now show that the encoding is lossless. Consider the first $\rho$ symbols of $S'$. Let $i_1 \leq 4k$ be the number of these symbols that must be deleted. It follows that the remaining $\rho - i_1$ symbols of $S'$ must be aligned against the symbols of $S[\rho + 1, n]$. Therefore, using the encoding, we can restore (at least) the first $\rho - i_1$ symbols of $S[\rho + 1, n]$ and consequently $S'[1, 2\rho - i_1]$. (Recall that insertions and replacements are stored in the encoding explicitly.)

2.2 Communication complexity protocol

We first explain what Charlie sends to Alice, and what Alice sends to Bob. Let $B = k\sqrt{n \log n}$ and $n_B = \lceil n/B \rceil$. Charlie sends to Alice document exchange sketches for each prefix $P[1, (n_B - i) \cdot B]$ and for each suffix $P[(n_B - i) \cdot B + 1, n]$.

We use deterministic document exchange sketches of size $O(k^2 + k \log^2 n)$ bits [15]. We use deterministic document exchange sketches of size $O(k^2 + k \log^2 n)$ bits [15]. (We note that using $O(k \log n)$-space sketches [15] would not improve the complexity but would drastically increase the computation time for Alice and Bob. For this reason, even though time is not the focus of this work, we
Let $i$ be the first block containing two $k$-mismatch occurrences of $P[1, (n_B - i) \cdot B]$ that start at least $2k$ positions apart. To compute the edit distances in a block $j < i$ Bob divides the pattern into two parts, a prefix $P[1, \ell]$ and the suffix $P[\ell + 1, n]$, and computes the distance for each of the two parts separately.

![Figure 1](image-url) Let $i$ be the first block containing two $k$-mismatch occurrences of $P[1, (n_B - i) \cdot B]$ that start at least $2k$ positions apart. To compute the edit distances in a block $j < i$ Bob divides the pattern into two parts, a prefix $P[1, \ell]$ and the suffix $P[\ell + 1, n]$, and computes the distance for each of the two parts separately.

prefer the sketches [1].) Alice starts by dividing her half of the text into non-overlapping blocks of length $B$ except for the last one which may be shorter, that is in total there are $n_B$ blocks.

**Definition 6.** A position $p$ of a block $i$ is $k$-good if it is the left endpoint of a $k$-mismatch occurrence of $P[1, (n_B - i) \cdot B]$.

Alice considers each block $i$ in turn and finds all $k$-good positions in the block using the pattern sketches. Suppose first that all $k$-good positions in the block are at distance $< 4k$. In this case all $k$-mismatch occurrences of $P[1, (n_B - i) \cdot B]$ that start in these positions end in an interval of length at most $6k$. For each position in this interval Alice finds the substring that ends in it and has the smallest edit distance from $P[1, (n_B - i) \cdot B]$ (using the pattern sketches again) and sends the distance and the corresponding edit operations to Bob. In total this information occupies $O(k^2 \log n)$ bits per block. Suppose now that block $i$ contains two $k$-good positions $p_1, p_2$, where $p_2 - p_1 > 4k$, and let $i$ be the first such block. Let $\ell = (n_B - i) \cdot B$ and let $ED$ be the edit distance between two strings.

**Lemma 7.** The $4k$-period of $T[p_1, p_2 + \ell - 1]$ is at most $B$.

**Proof.** By the definition both $p_1$ and $p_2$ are starting positions of $k$-mismatch occurrences of $P[1, \ell]$. Therefore, $ED(T[p_1, p_1 + \ell - 1], P[1, \ell]) \leq 2k$ and $ED(T[p_2, p_2 + \ell - 1], P[1, \ell]) \leq 2k$. From the triangle inequality it follows that $ED(T[p_1, p_1 + \ell], T[p_2, p_2 + \ell - 1]) \leq 4k$ and from the definition of approximate periods it follows that the $4k$-period of $T[p_1, p_2 + \ell - 1]$ is at most $B$.

By Lemma 5 the substring $T[p_1, p_2 + \ell - 1]$ and therefore $T[p_1, n - B]$ can be encoded in $O(B + k \log n)$ bits. Alice sends the encoding to Bob (note that she only does it for the first block containing distant $k$-good positions). Finally, she sends Bob the last $(B + k)$ symbols of her half of the text and also forwards the sketches received from Charlie. The total size of Alice’s message is $O((n/B) \cdot k^2 \log^2 n + B) = O(k \sqrt{n} \log n)$ bits.

We now explain how Bob computes the distances. Suppose that he wants to compute the edit distance between the pattern a substring starting to the left of position $p_1$. Using the encoding of $T[p_1, n - B]$, the last $B$ symbols of Alice’s half of the text, and his half of the text he can restore all symbols of $T[p_1, 2n]$. He can then use the pattern sketch to compute the edit distance and operations. Consider now the case when the substring starts in a block $j < i$ (see Fig. 1). Let $S$ be the substring for which Bob wants to compute the edit distance and $\ell = (n_B - j) \cdot B$. Bob starts by dividing the pattern into two parts, a prefix $P[1, \ell]$ and the suffix $P[\ell + 1, n]$. The following observation is a corollary of the definition of the edit distance.
The algorithm processes the text in blocks of size $B$. To decide whether the current stream ends with a $k$-mismatch occurrence of $P$, the algorithm divides the pattern into two parts, a prefix of length at most $B + k$ and the remaining suffix and computes the edit distance for each of the parts separately.

\begin{figure}[h]
\centering
\includegraphics[scale=0.5]{algorithm_diagram.png}
\caption{The algorithm processes the text in blocks of size $B$. To decide whether the current stream ends with a $k$-mismatch occurrence of $P$, the algorithm divides the pattern into two parts, a prefix of length at most $B + k$ and the remaining suffix and computes the edit distance for each of the parts separately.}
\end{figure}

\begin{observation}
Let $\Delta = \min_{\ell' \in [\ell-k,\ell+k]} \{ ED(P[1,\ell],S[1,\ell']) + ED(P[\ell+1,n],S[\ell'+1,n]) \}$. If $\Delta > k$, then the edit distance between $S$ and $P$ is larger than $k$, and otherwise it is equal to $\Delta$.
\end{observation}

Since $j < i$, Bob knows all positions $\ell'$ of $S$ for which there exists a $k$-mismatch occurrence of $P[1,\ell]$ ending at this position (and also the edit operations that convert the occurrence into $P[1,\ell]$). On the other hand, since Bob knows the last $B + k$ symbols of Alice’s half of the text, he knows $S[\ell'+1,n]$ and can use the sketch of $P[\ell+1,n]$ to compute the edit distance and the edit operations between the two. He can therefore decide if $S$ is a $k$-mismatch occurrence of $P$ and the edit operations that transform $S$ into $P$.

\section{Streaming}
We now show a streaming algorithm for approximate pattern matching. As soon as a new symbol arrives we must decide if the current stream ends with a $k$-mismatch occurrence of $P$ and output the edit operations between $P$ and the occurrence. The algorithm processes the text by blocks of size $B = \sqrt{n}$ (see Fig. 2). Suppose that the text ends with a $k$-mismatch occurrence of the pattern $P$. This occurrence can be divided into two parts, a prefix of length at most $B$, and a suffix that starts at a block border. From Observation 8 it follows that there exists a position $i \in [1,B+k]$ such that the prefix of the occurrence must be aligned with $P[1,i]$, and the suffix of the occurrence must be aligned with $P[i+1,n]$. The algorithm will therefore need to be able to compute the edit distances between each block and prefixes $P[1,i]$, and the edit distances between suffixes of the text starting at block borders and suffixes $P[i+1,n]$.

\subsection{Prefixes}
Consider a block of the text $T$. For each $i$ such that the block ends with a $k$-mismatch occurrence of $P[1,i]$ we define $S_i$ to be the suffix of the block with the smallest edit distance from $P[1,i]$. Below we will show a hybrid dynamic programming algorithm that computes all suffixes $S_i$, the corresponding edit distances and edit operations in $O((B+k) \cdot k)$ space and in $O(k)$ time per symbol of the block. But first, let us explain how we apply it. Note that the suffixes $S_i$, the distances and the operations will be used only $n/B$ blocks later. A naive approach would be to compute all this information and to store it explicitly until that time. However, the total space requirement of this approach is too large. Instead, we develop a different approach which runs the algorithm twice. Upon having received a new text block, we run the algorithm for the first time and compute suffixes $S_i$ for all $i \in [1,B+k]$. Let
Figure 3 The graph shows a 3-path that encodes the edit operations between $P[1,5] = 01011$ and a suffix 00110 of the block. The three red arrows show the edit operations: a replacement, an insertion, and a deletion.

$S^* = S_j$ be the longest of the retrieved suffixes. We encode the block as a tuple consisting of the position $j$, and the at most $k$ edit operations that transform $P[1,j] = 01011$ into $S^*$ (see also Introduction). After having read $n/B - 2$ more blocks we use the encoding and $P[1,B+k]$ to restore $S^*$ and then run the algorithm on $S^*$ to compute the suffixes $S_i$ and the corresponding edit operations.

We now describe our algorithm. The algorithm uses the same approach as the hybrid dynamic programming algorithms for the approximate pattern matching problem [12, 13] (see also [10, Chapter 12.2.4]). We assume that $P[1,B+k]$ is stored explicitly. The algorithm receives as an input a text block of length $\leq B$. The algorithm starts by preprocessing the $P[1,B+k]$ and the block for longest common extension queries. For a pair of positions $(p_1,p_2)$, a longest common extension query finds the longest substring starting at position $p_1$ of the block that matches a substring starting at position $p_2$ of $P[1,B+k]$. The preprocessing phase takes $O(B+k)$ time and space [9]. The algorithm then considers a table of size $(B+k+1) \times (B+1)$ and builds a set of paths from the first row to the last column of the table. Each such path will correspond to a suffix of the block that is a $k$-mismatch occurrence of $P[1,i]$ and encode the edit operations that transform the suffix into $P[1,i]$.

The algorithm runs in $k$ rounds. In round $m$, $1 \leq m \leq k$, it processes each of the diagonals of the table in turn and finds a path that corresponds to at most $m$ edit operations ($m$-path) and ends in the lowest cell in the current diagonal. Each of the paths starts in one of the cells in the first row of the table. From a cell $(p_1,p_2)$ a path can go either to a cell $(p_1+1,p_2)$, or to $(p_1,p_2+1)$, or to $(p_1+1,p_2+1)$. Let $a$ be the $(p_1+1)$-th symbol of the block and $b$ be the $(p_2+1)$-th symbol of the pattern. A move to $(p_1+1,p_2)$ corresponds to deletion of $a$, a move to $(p_1,p_2+1)$ to insertion of $b$, and a move to $(p_1+1,p_2+1)$ to a replacement of $a$ by $b$ if $a \neq b$. If symbols $a,b$ are not edited, the path makes a diagonal step as well. Suppose that in round $m$, $m \leq k$, a path reaches a cell $(B,i)$ of the last column of the table for the first time. From construction it follows that this path corresponds to the suffix $S_i$.

It remains to explain how the algorithm finds the $m$-paths. Consider a diagonal $i$. To find the $m$-path that ends in the lowest cell in the diagonal, the algorithm tries to extend the $(m-1)$-paths for diagonals $i-1$, $i$, and $i+1$. Consider first the $(m-1)$-path for
diagonal $i$. Suppose that it ends in a cell $(j, j + i)$. The algorithm makes a step from $(j, j + i)$ to $(j + 1, j + i + 1)$ that corresponds to a replacement of a symbol and then tries to extend the path further down along the diagonal until it meets the next pair of mismatching symbols. Note that this step can be performed in $O(1)$ time using a longest common extension query. The $(m - 1)$-paths in diagonals $i - 1$ and $i + 1$ are extended in a similar fashion, except that from the end of the $(m - 1)$-path in diagonal $i + 1$ the algorithm makes a horizontal step (corresponds to a deletion of a symbol of the block) and from the end of the $(m - 1)$-path in diagonal $i + 1$ the algorithm makes a vertical step (corresponds to an insertion of a symbol). It is not hard to see that in this way the algorithm finds the end of the $m$-path for a fixed diagonal in $O(1)$ time, meaning that overall the algorithm uses $O((B + k) \cdot k)$ time and $O((B + k) \cdot k)$ space per block.

\textbf{Remark.} Note that the running time of the algorithm can be de-amortised to spend $O(k)$ time per arrival in the worst case: When we apply the algorithm to a block $i$ for the first time, we de-amortise its running time over block $i + 1$ by running $\Omega(k)$ steps of the algorithm each time a new block symbol arrives, and when we run the algorithm for the second time we de-amortise its running time over block $i + n/B - 2$.

### 3.2 Suffixes

To compute the distances from suffixes of the pattern to the text the algorithm uses sketches by Belazzougui and Zhang [2, Theorem 13].

\textbf{Theorem 9 ([2])}. Assume $k < n^{1/c}$ for some sufficiently large constant $c > 0$. There is a sketch of size $O(k^3 \log^3 n)$ that can be used to compute the edit distance between two binary strings of length at most $n$ in $O(k^2 \log^3 n)$ time correctly with probability $0.9$. Given a string arriving as a stream its sketch can be constructed in $O(k^3 \log^3 n)$ amortised time per symbol.

The space and time bounds are not given in [2, Theorem 13] but can be derived from its proof. We will show the following corollary.

\textbf{Corollary 10}. Assume $k < n^{1/c}$ for some sufficiently large constant $c > 0$. There is a sketch of size $O(k^3 \log^3 n)$ that can be used to compute the edit distance between two binary strings of length at most $n$ in $O(k^2 \log^3 n)$ time correctly with probability $1 - \text{poly}(n)$. Given a string arriving as a stream its sketch can be constructed in $O(k^2 \log^4 n)$ worst-case time per symbol.

We boost the probability of Theorem 13 [2] from $0.9$ to $1 - \text{poly}(n)$ in a standard way, by repeating the computation independently $O(\log n)$ times and taking the smallest edit distance as an answer, which yields the extra $\log n$ factors in the complexities.

For completeness and to explain how to de-amortise the time bound, we give the definition of the sketches. The sketches are constructed using a random walk embedding from edit to Hamming distance [4]. The embedding maps strings of length $n$ onto strings of length $3n$. Consider a string $S$ and set a pointer to $S[1]$. At each step, the embedding copies the symbol at which the pointer is currently at to the resulting string $E(S)$ and either moves the pointer to the right or stays in place. After having reached the end of $S$ it stops, and if the length of $E(S)$ is $\ell < 3n$, it appends $3n - \ell$ zeros to it. The moves of the pointer are defined by a random string $R \in \{0, 1\}^{3n}$. If $i$ is the current position of the pointer in $S$, and $j$ is the length of $E(S)$, then the pointer moves to the right if $R[S[i] + 2j] = 1$ and otherwise it stays in place.
The intuition behind the proof is that the difference between the pointers’ positions as they move along two strings $S_1, S_2$ behaves as a one-dimensional random walk. In more details, since $R$ is a random binary string, at each time moment when the difference is not zero and there is a mismatch between $E(S_1)$ and $E(S_2)$ the difference does not change with probability $1/2$, increases by one with probability $1/4$, and decreases by one with probability $1/4$.

The mismatched symbols of $E(S_1)$ and $E(S_2)$ and their respective positions in $S_1$ and $S_2$ can be used to construct a set of edit operations that transform $S_1$ to $S_2$. The set might be not optimal, but it gives some evidence of which positions in $S_1$ and $S_2$ must be edited. Belazzougui and Zhang first developed sketches of the embeddings $E(S_1), E(S_2)$ that allow to retrieve both the mismatched symbols and their positions in $S_1$ and $S_2$. Their sketches are based on the Hamming distance sketches of Porat and Lipsky [17] and can be constructed in $O(\log^2 n)$ worst-case time per symbol of an embedding. They further suggested to consider $O(k^2 \log^2 n)$ independent random walk embeddings and showed that they give enough information to derive the optimal set of edit operations.

To de-amortise the time bound of Theorem 13 [2] we notice that in the random walk embedding a pointer advances by at least one position of the initial string each $3 \log n$ steps with probability at least $1 - 1/n^3$. Therefore if the sketch construction algorithm gets stuck at some position for more than $3 \log n$ steps, we can simply abandon it. This incomplete sketch might result in erroneous outputs, but the probability of this event is small.

### 3.3 Algorithm

We are now ready to give a full description of the algorithm. We assume that the algorithm first receives the pattern and preprocesses it in a streaming fashion. Namely, it remembers the first $B + k$ symbols of the pattern and also computes sketches of each suffix $P[i, n]$, $i \in [1, B + k]$. The sketches occupy $O((B + k) \cdot k^8 \log^6 n)$ space in total.

After a new block of the text has arrived, the algorithm computes its encoding defined in Section 3.1. In total all block encodings occupy $O((n/B) \cdot k \log n)$ space. Also, while reading block $i$, the algorithm decodes block $i + 2 - n/B$ and runs the algorithm of Section 3.1 to compute the edit distances for the prefixes of $P$. Recall that this step can be de-amortised to take $O(k)$ worst-case time per arrival. Finally, the algorithm considers each of the suffixes of the current text that starts at a block border as a separate stream and computes its sketch in a streaming manner. That is, when a new symbol $T[j]$ arrives the algorithm updates each of the $O(n/B)$ suffix streams and each of its sketches in $O((n/B) \cdot k^2 \log^4 n)$ time. The suffix sketches occupy $O((n/B) \cdot k^8 \log^6 n)$ space in total.

We finally explain how the algorithm computes an output for a new arrival $T[j]$ in a block $i$. Recall that the task is to decide if $T[1, j]$ ends with a $k$-mismatch occurrence of $P$ and if so to output the edit operations between the pattern and the occurrence. The length of the occurrence must be in $[n - k, n + k]$. It therefore starts either in block $i - n/B$ or in block $i + 1 - n/B$. The two cases are analogous and we consider only the case when the occurrence starts in block $i - n/B$. Let $S$ be the suffix of $T[1, j]$ starting at the right border of block $i - n/B$ (in Fig. 2 the suffix is shown in green). $S$ must be aligned with one of the $2k$ suffixes of the pattern of length in $[|S| - k, |S| + k]$. Using the sketches, we compute the edit distances (and the edit operations) from each of these suffixes to $S$. Consider a suffix...
\( P[i+1, n] \). If it is aligned with \( S \), the prefix \( P[1, i] \) must be aligned with some suffix of block \( i - n/B \) and we have computed the minimal edit distance from \( P[1, i] \) to the block or we know that it is larger than \( k \). For each \( i \), we sum the edit distances for the prefix and for the suffix and take the minimum. If the minimum is smaller than \( k \), then by Observation 8 \( T[1, j] \) ends with a \( k \)-mismatch occurrence of the pattern \( P \) and we can output the edit distance and the edit operations. In total, this step takes \( \mathcal{O}(k^{13} \log^4 n) \) time.

We choose \( B = \sqrt{n} \). The space complexity of the algorithm is then \( \mathcal{O}(k^8 \sqrt{n} \log^6 n) \). The time for updating the sketches is \( \mathcal{O}(k^2 \sqrt{n} \log^4 n) \) per arrival, and the time for computing the edit distance is \( \mathcal{O}(k^{13} \log^4 n) \), meaning that the total time complexity is \( \mathcal{O}((k^2 \sqrt{n} + k^{13}) \log^4 n) \) per arrival.

### 4 Conclusion

In this work we studied the approximate pattern matching problem. In particular we showed the first sublinear-space streaming algorithm for the problem. The space complexity of our algorithm is \( \mathcal{O}(k^8 \sqrt{n} \log^6 n) \), which is significantly better than that of the previously known solutions. We note that on the other hand the time complexity of our algorithm is quite large as we have to update sketches of \( \sqrt{n} \) text suffixes each time a new symbol arrives. One possibility to improve the time complexity is to maintain sketches of the blocks of the text rather than sketches of the suffixes (this way, the algorithm will need to update only one sketch per arrival). However, it is not clear whether the block sketches can be used to compute suffix sketches and therefore the edit distance. This is because the moves of a pointer in a suffix block are not independent, in other words the image of a block under the random walk embedding depends on all preceding blocks. We leave this challenging question for further research.

Abstract

Inspired by a recent approach for genome reconstruction from incomplete data, we consider a
variant of the longest common subsequence problem for the comparison of two sequences, one of
which is incomplete, i.e. it has some missing elements. The new combinatorial problem, called
Longest Filled Common Subsequence, given two sequences \(A\) and \(B\), and a multiset \(M\) of symbols
missing in \(B\), asks for a sequence \(B^*\) obtained by inserting the symbols of \(M\) into \(B\) so that \(B^*\)
induces a common subsequence with \(A\) of maximum length.

First, we investigate the computational and approximation complexity of the problem and
we show that it is NP-hard and APX-hard when \(A\) contains at most two occurrences of each
symbol. Then, we give a \(\frac{5}{2}\)−approximation algorithm for the problem. Finally, we present a
fixed-parameter algorithm, when the problem is parameterized by the number of symbols inserted
in \(B\) that “match” symbols of \(A\).

1 Introduction

The comparison of sequences via Longest Common Subsequence (LCS) has been applied in
several contexts where we want to retrieve the maximum number of elements that appear in
the same order in two or more sequences. There are well-known fields of application of LCS
like scheduling and data compression, a notable example is the \textsc{diff} utility to compute the
differences between two files.

The extraction of common subsequences has been widely applied to compare molecular
sequences in bioinformatics [17, 14]. For example, the comparison of biological sequences
provides a measure of their similarities and differences, aiming at understanding whether
they encode similar/different functionalities. Different approaches for the comparison of two
The Longest Filled Common Subsequence Problem

genomes based on LCS have been considered in the last years, leading to variants of the longest common subsequence problem, like the constrained longest common subsequence [13, 8, 18, 11, 4] or the repetition-free longest common subsequence and variants thereof [7, 1, 6, 12].

The approaches based on LCS for genome comparison assume that the input sequences are complete, that is there are no missing data. However, while Next Generation Sequencing technologies are able to produce a huge amount of DNA/RNA fragments, the cost of reconstructing a complete genome is still high [10]. Hence, released genomes often contain errors or are incomplete. These incomplete genomes are called scaffolds. One approach to the reconstruction of genome is to fill scaffolds with missing genes, based on the comparison of an incomplete genome with a reference genome [16, 15, 9, 19]. Given an incomplete genome $B$, a set of missing genes (symbols) $M$ and a reference genome $A$, the goal is to insert the missing symbols in $B$ so that the number of common adjacencies between the resulting genome $B^*$ and $A$ is maximized. We have a common adjacency when two genes $a$, $b$ are consecutive both in $A$ and $B^*$, independently from the order. We mention briefly that there is also a variant of the scaffold filling approach that compares two incomplete genomes [15, 9].

Inspired by methods for genome comparison based on LCS and by the scaffold filling approach, we introduce a new variant of the LCS problem, called the Longest Filled Common Subsequence problem, for the comparison of a complete genome $A$ and an incomplete genome $B$. The goal of the problem is to find the maximum number of genes that appear in the same order in both genomes. However, since some of the genes in $B$ are missing (a multiset $M$ of symbols), we have to compute a longest common subsequence of $A$ and of a filling $B^*$ of $B$, that is of a sequence obtained from $B$ by inserting the symbols of $M$ into $B$. Notice that while the scaffold filling problem aims to reconstruct a complete genome from an incomplete one by maximizing the number of common adjacencies, here we aim to infer only those elements (genes) that appear in the same order in the complete genome $A$ and in the completed genome $B^*$.

In this paper, we investigate different algorithmic and complexity aspects of the Longest Filled Common Subsequence problem. First, in Section 3 we prove that it is NP-hard and APX-hard, even when genome $A$ contains at most two occurrences of each symbol. Notice that bounding the maximum number of occurrences of symbols in a sequence is relevant in this case, as usually the number of copies of a gene inside a genome is bounded. Then, in Section 4 we present a polynomial-time approximation algorithm of factor $\frac{3}{5}$. In Section 5, we give a fixed-parameter algorithm, where the parameter is the number of inserted symbols that lead to a “match” with symbols of sequence $A$. Such a parameter can be of interest when the number of missing elements, and in particular those that lead to a “match” with symbols of $A$, is moderate, as the complexity of the algorithm depends exponentially only on this parameter.

Some of the proofs are omitted due to page limit.

2 Preliminaries

In this section we introduce some basic definitions that will be useful in the rest of the paper and we give the formal definition of the Longest Filled Common Subsequence problem. Let $S$ be a sequence over an alphabet $\Sigma$, we denote by $|S|$ the length of $S$. Given a position $i$, with $1 \leq i \leq |S|$, we denote by $S[i]$ the symbol in position $i$ of $S$. Given two positions $i$, $j$ in $S$, with $1 \leq i \leq j \leq |S|$, we denote by $S[i,j]$ the substring of $S$ that starts at position $i$ and ends at position $j$. Given two sequences $S$ and $T$, we denote by $S \cdot T$ the sequence that results by concatenating $S$ and $T$. 
A subsequence of $S$ is a sequence $S'$ that is obtained from $S$ by deleting some symbols (possibly none). A common subsequence $S$ of two sequences $A$ and $B$ is a subsequence of both $A$ and $B$. A longest common subsequence of $A$ and $B$ is a common subsequence of $A$ and $B$ having maximum length.

Given two sequences $A$ and $B$, a common subsequence can be defined by aligning $A$ and $B$ and by connecting two positions of $A$ and $B$ containing an identical symbol with a line, such that there is no pair of crossing lines. This is called a threading schema (see Fig. 1). Given a threading schema for sequences $A$, $B$, a connection between two symbols in $A$ and $B$, respectively, is called a match and the two positions incident in a line are said to be matched.

Given a sequence $S$ and a multiset of symbols $M$, we define a filling of $S$ with $M$ as a sequence $S'$ obtained by inserting a subset $M'$ of symbols of $M$ into $S$. Notice that in a filling of $S$ with $M$ not all the symbols of $M$ have to be inserted in $S$. Informally, we may not insert those symbols that do not induce matches, to simplify the algorithms we describe in Section 4 and in Section 5. Now, we are ready to present the formal definition of Longest Filled Common Subsequence.

\[\text{Problem 1. Longest Filled Common Subsequence (LFCS)}\]

\textbf{Instance:} two sequences $A$ and $B$ over an alphabet $\Sigma$, and a multiset $M$ over $\Sigma$.

\textbf{Solution:} a filling $B^*$ of $B$ with $M$.

\textbf{Measure:} the length of a longest common subsequence of $A$ and $B^*$ (to be maximized).

Given two sequences $A$, $B$ and a multiset $M$ over $\Sigma$, let $B^*$ be a filling of $B$ with $M$. Consider a common subsequence of $A$ and $B^*$, and their corresponding threading schema. A position of $A$ can have two possible kinds of matches (see Fig. 2): a match with a position of $B^*$ that contains a symbol of $M$ inserted in $B$, called match by insertion, or a match with a position of $B^*$ not involved in an insertion, called match by alignment. We can easily compute in polynomial-time two upper bounds on the number of positions of $A$ that can be matched by alignment and by insertion, that will be useful in Section 4. The first upper bound is related to a longest common subsequence $L$ of $A$ and $B$, which can be computed in polynomial time. In fact, the maximum number of positions of $A$ (and of a filling $B^*$ of $B$ with $M$) that are matched by alignment is at most the length of $L$.

Next we show how to compute in polynomial-time an upper bound on the number of positions of a sequence $A$ that can be matched by insertion. First, given a multiset $M$ of symbols, we define an ordering of $M$ as a sequence obtained by defining an order among each element of $M$, that is each occurrence of a symbol of $M$.

Consider the positions of $A$ and of a filling $B^*$ of $B$ with $M$ that are matched by insertion; the positions of $A$ induce a subsequence $A'$ of $A$, while the positions of $B^*$ induce an ordering $M$ of a subset $M' \subseteq M$. An upper bound on the length of $M$ can be computed in polynomial time with the following greedy algorithm.

\begin{figure}[h]
\centering
\includegraphics[width=0.8\textwidth]{threading_schema.png}
\caption{The threading schema of two sequences $A$ and $B$: lines connect matched positions of $A$ and $B$.}
\end{figure}
The Longest Filled Common Subsequence Problem

Figure 2 A filling $B^*$ of sequence $B$ in Fig. 1, computed by inserting a symbol in position 2 (symbol $b$) and a symbol in position 3 (symbol $c$), both in grey. A subsequence of $A$ and $B^*$ is induced by the threading schema of $A$ and $B^*$, where straight lines represent matches by alignment, dashed lines represent matches by insertion.

Algorithm 1:
Data: $A$, $M$
Result: a subsequence $A'$ of $A$ that matches the maximum number of symbols of a sequence $M$ obtained by ordering $M$

1. $i := 1$;
2. $A'$ is an empty sequence;
3. while $i \leq |A|$ do
   4. if $\alpha \in M$ with $A[i] = \alpha$ then
      5. $A' := A' \cdot \alpha$;
      6. $M := M \{\alpha\}$;
   7. $i := i + 1$;

Next, we prove the correctness of Algorithm 1.

Lemma 1. Given a sequence $A$, a multiset $M$ on $\Sigma$, and a substring $A[1,i]$ of $A$, Algorithm 1 computes a subsequence of $A[1,i]$ that matches the maximum number of symbols of an ordering $M$ of $M$.

3 Complexity of $\mathcal{LFC}$

In this section, we investigate the computational (and approximation) complexity of the $\mathcal{LFC}$ problem, and we prove that it is APX-hard when $A$ contains at most two occurrences of each symbol in $\Sigma$ (we denote this restriction of $\mathcal{LFC}$ by $2$-$\mathcal{LFC}$). We prove the result by an L-reduction from the Maximum Independent Set problem on Cubic Graphs (Max-ISC), which is known to be APX-hard [2](see [5] for details on L-reduction). Max-ISC, given a cubic graph $G = (V,E)^1$, asks for a maximum cardinality subset $V' \subseteq V$ such that given $v_i, v_j \in V'$ it holds $\{v_i,v_j\} \notin E$.

Given a cubic graph $G = (V,E)$, with $V = \{v_1, v_2, \ldots, v_n\}$ and $|E| = m$, in the following we show how to construct an instance $(A, B, M)$ of $2$-$\mathcal{LFC}$. Define an order on the edges incident on a vertex $v_i$ in $V$ assuming $\{v_i,v_j\} < \{v_i,v_k\}$ if $j < h$. Given a vertex $v_i$, and the edges $\{v_i, v_j\}, \{v_i, v_k\}, \{v_i, v_z\} \in E$, with $j < h < z$, we say that $\{v_i,v_j\}$ ($\{v_i,v_k\}, \{v_i,v_z\}$, respectively) is the first (second, third, respectively) edge incident on $v_i$.

First, we define the alphabet $\Sigma$:

$\Sigma = \{x_{i,j} : v_i \in V, 1 \leq j \leq 3\} \cup \{y_{i,j} : v_i \in V, 1 \leq j \leq 2\} \cup \{z_{i,j} : 1 \leq i \leq n+m-1, 1 \leq j \leq 4\}.$

1 We recall that a cubic graph is an undirected graph where each vertex has degree exactly three.
The input sequences $A$ and $B$ are built by concatenating several substrings.

For each $v_i \in V$, we define the following substrings of the input sequences $A$, $B$:

$$A(v_i) = y_{i,1}x_{i,1}x_{i,2}x_{i,3}, \quad B(v_i) = x_{i,1}x_{i,2}x_{i,3}y_{i,1}y_{i,2}.$$ 

For each $\{v_i, v_j\} \in E$, with $i < j$ (which is the $p$-th edge, $1 \leq p \leq 3$, incident on $v_i$ and the $q$-th edge, $1 \leq q \leq 3$, incident on $v_j$), define the following substrings of $A$, $B$:

$$A(\{v_i, v_j\}) = x_{i,p}x_{j,q}, \quad B(\{v_i, v_j\}) = x_{j,q}x_{i,p}.$$ 

Finally, define $2(n + m - 1)$ additional substrings $S_{A,1}, S_{A,2}, \ldots, S_{A,m+n-1}, S_{B,1}, S_{B,2}, \ldots, S_{B,m+n-1}$ where $S_{A,i}, S_{B,i}$, with $1 \leq i \leq m + n - 1$, are defined as follows:

$$S_{A,i} = S_{B,i} = z_{i,1}z_{i,2}z_{i,3}z_{i,4}.$$ 

Now, we are able to define the input sequences $A$ and $B$, by concatenating the substrings previously defined, where substrings associated with edges of $G$ are concatenated assuming some edge ordering (we assume that $\{v_1, v_w\}$ is the first edge, while $\{v_r, v_j\}$ is the last edge according to the ordering):

$$A = A(v_1) \cdot S_{A,1} \cdot A(v_2) \cdot \cdots \cdot A(v_{m+n-1}) \cdot A(\{v_1, v_w\}) \cdots \cdot S_{A,m+n-1} \cdot A(\{v_r, v_j\}),$$

$$B = B(v_1) \cdot S_{B,1} \cdot B(v_2) \cdot \cdots \cdot B(v_{m+n-1}) \cdot B(\{v_1, v_w\}) \cdots \cdot S_{B,m+n-1} \cdot B(\{v_r, v_j\}).$$

Notice that each substring associated with an edge $\{v_i, v_j\}$ appears exactly once in both $A$ and $B$.

$\mathcal{M}$ (in this case is a set) is defined as follows:

$$\mathcal{M} = \{x_{i,t} : v_i \in V, 1 \leq t \leq 3\}.$$ 

First, we prove that $(A, B, \mathcal{M})$ is an instance of 2-$\text{LFCS}$, that is we prove that each symbol has at most two occurrences in $A$.

**Lemma 2.** Each symbol of $\Sigma$ occurs at most twice in $A$.

**Proof.** Notice that each symbol appearing in a substring $S_{A,i}$, $1 \leq i \leq m + n - 1$, does not appear in any other subsequence of $A$. Now, consider a symbol $y_{i,t}$, $1 \leq i \leq n$ and $1 \leq t \leq 2$, appearing in substring $A(v_i)$; $y_{i,t}$ does not appear in any other substring of $A$. Finally, consider a symbol $x_{i,t}$, $1 \leq i \leq n$ and $1 \leq t \leq 3$, $x_{i,t}$ has one occurrence in exactly two subsequences of $A$: subsequence $A(v_i)$ and subsequence $A(\{v_i, v_j\})$ (where $\{v_i, v_j\}$ is the $t$-th edges incident on $v_i$).

Let $B^*$ be a solution of 2-$\text{LFCS}$ over instance $(A, B, \mathcal{M})$. We denote by $S_{B,1}^+ (B^*(v_i), B^*(\{v_i, v_j\}))$, respectively), the substring of a solution $B^*$ corresponding (after some insertion) to the substring $S_{B,i}^+ (B(v_i), B(\{v_i, v_j\}))$, respectively, of $B$.

Next, we show that we can assume that in a solution $B^*$ of 2-$\text{LFCS}$ over instance $(A, B, \mathcal{M})$, a longest common subsequence of $A$ and $B^*$ matches by alignment a position of a subsequence $S_{A,i}$, $1 \leq i \leq m + n - 1$, only with a position of $S_{B,1}^+$, $1 \leq i \leq m + n - 1$.

**Lemma 3.** Given a cubic graph $G$, let $(A, B, \mathcal{M})$ be the corresponding instance of 2-$\text{LFCS}$, and $B^*$ a solution of 2-$\text{LFCS}$ over $(A, B, \mathcal{M})$. Then a longest common subsequence of $A$ and $B^*$ contains each symbol $z_{t,q}$, with $1 \leq t \leq m + n - 1$ and $1 \leq q \leq 4$.

**Proof.** Consider a solution $B^*$ of 2-$\text{LFCS}$ over instance $(A, B, \mathcal{M})$ and assume that it does not contain a symbol $z_{t,q}$, with $1 \leq t \leq m + n - 1$ and $1 \leq q \leq 4$. By construction a longest common subsequence of $B^*$ and $A$ matches by alignment a position of $A(v_i)$ either with a position of $B(v_i)$ or with a position of $B(\{v_i, v_j\})$. 

First, we prove that a longest common subsequence between $A$ and $B^*$ matches by alignment a position of $A(v_i)$ only with a position of $B(v_i)$. Assume that $i$ is the minimum value such that a longest common subsequence $S$ of $A$ and $B^*$ matches by alignment a position of $A(v_i)$ and a position of $B^*\{v_i, v_j\}$. Notice that, by construction of $(A, B, M)$, no position of $S_{A_i}$ can be matched. Now, starting from $S$ we can compute a common subsequence $S'$ of $A$ and $B^*$, with $|S'| > |S|$, by modifying the alignment of $S$ as follows: (i) match by alignment the positions of $A(v_i)$ and the positions of $B^*\{v_i\}$ containing symbols $y_{i,1}, y_{i,2}$; (ii) match by alignment the positions of subsequences $S_{A_i}$ containing symbol $z_{i,q}$ with position of subsequences $S_{B_i}$ containing symbol $z_{i,q}$; (iii) any other match is not modified. It follows that the number of positions in $A(v_i)$ matched by $S'$ with respect to $S$ is decreased by at most three, since eventually positions of $A(V_i)$ containing symbols $x_{i,1}, x_{i,2}, x_{i,3}$ will not be matched. The number of positions in $S_{A_i}$ matched by $S'$ with respect to $S$ is increased by at least $3$, since each position of $S_{A_i}$ is not matched by $S$ and it is matched by $S'$. By iterating this procedure, we eventually find a longest common subsequence $S'$ of $A$ and $B^*$ where if each position of $A(V_i)$ is matched by alignment, then it is matched with a position of $B(v_i)$. By the maximality of $S'$, this implies that each position of $A$ containing a symbol $z_{i,q}$, with $1 \leq t \leq m + n - 1$ and $1 \leq q \leq 4$, matches a position of $B^*$ containing symbol $z_{i,q}$.

Consider a vertex $v_i \in V$ and the corresponding substrings $A(v_i), B(v_i)$ of $A$ and $B$. Moreover, let $\{v_i, v_j\}, \{v_i, v_h\}, \{v_i, v_z\} \in E$ be the three edges of $G$ incident on $v_i$ and consider the corresponding substrings $A(\{v_i, v_j\}), A(\{v_i, v_h\}), A(\{v_i, v_z\}) = B(\{v_i, v_j\}), B(\{v_i, v_h\}), B(\{v_i, v_z\})$, respectively, of $A$ (of $B$, respectively). Informally, the reduction shows that there are essentially two possible configurations (called $I$-configuration and $C$-configuration) of the substring $B^*\{v_i\}$ (and possibly $B^*\{v_i, v_j\}, B^*\{v_i, v_h\}$ and $B^*\{v_i, v_z\}$) of a filling $B^*$ of $B$. A substring $B^*\{v_i\}$ having an I-configuration is related to the vertex $v_i$ in an independent set of $G$, while a substring $B^*\{v_i\}$ having a C-configuration is related to the vertex $v_i$ in a vertex cover of $G$.

We define now the two possible configurations, called $I$-configuration and $C$-configuration, for $B^*\{v_i\}$ and, possibly, for the substrings $B^*\{v_i, v_j\}, B^*\{v_i, v_h\}$ and $B^*\{v_i, v_z\}$ of a filling $B^*$ of $B$. An $I$-configuration for the substrings $B^*\{v_i\}, B^*\{v_i, v_j\}, B^*\{v_i, v_h\}$ and $B^*\{v_i, v_z\}$ is defined as follows:

- $B^*\{v_i\} = B(v_i)$ (hence there is no insertion in $B(v_i)$).

- For each $\{v_i, v_j\}$, with $t \in \{j, h, z\}$, where $v_i, v_j$ is the $p$-th edge incident on $v_i$, $1 \leq p \leq 3$, and the $q$-th edge incident on $v_i, 1 \leq q \leq 3$, $B^*\{v_i, v_j\} = x_{i,p}x_{j,q}$, $B^*\{v_i, v_z\}$ (hence $x_{i,p}$ is inserted in $B(\{v_i, v_j\})$).

If $B^*\{v_i\}, B^*\{v_i, v_j\}, B^*\{v_i, v_h\}, B^*\{v_i, v_z\}$ have an I-configuration, a longest common subsequence of $B^*\{v_i\}$ and $A(v_i)$ has length three (it matches the positions containing $x_{i,1}, x_{i,2}, x_{i,3}$), and a longest common subsequence of $A(\{v_i, v_j\})$ and $B^*\{v_i, v_z\}$, with $t \in \{j, h, z\}$, has length two (it matches the positions containing $x_{i,p}, x_{j,q}$).

A $C$-configuration for the substring $B^*\{v_i\}$ is defined as follows:

- $B^*\{v_i\} = x_{i,1,2,3}y_{i,1,2,3}x_{i,1,2,3}$ (hence $B^*\{v_i\} = B(v_i) : x_{i,1,2,3}$).

If $B^*\{v_i\}$ has a C-configuration, a longest common subsequence of $B^*\{v_i\}$ and $A(v_i)$ has length five, it matches the positions containing $y_{i,1}, y_{i,2}, x_{i,1}, x_{i,2}, x_{i,3}$.

Next, we present the main lemmata of this section.

Lemma 4. Let $G$ be a cubic graph, instance of Max-ISC, and let $(A, B, M)$ be the corresponding instance of $2-LFCS$. Then, given an independent set $I$ of $G$, we can compute
in polynomial time a solution $B^*$ of $2\text{-LFCS}$ over instance $(A,B,M)$ inducing a longest common subsequence with $A$ of length $4(m + n - 1) + 6|I| + 5(n - |I|) + m$.

**Proof.** Consider an independent set $I$ and define a solution $B^*$ of $2\text{-LFCS}$ over instance $(A,B,M)$ as follows. For each $v_i \in I$, with $\{v_i, v_j\}, \{v_i, v_h\}, \{v_i, v_z\} \in E$ the three edges of $G$ incident on $v_i$, define an I-configuration for $B^*(v_i)$. By Lemmata 4 and 5, and by the APX-hardness of Max-ISC [2] we can conclude that $\sum_{v_i \in I} |B^*(v_i)|$ is well-defined, as each position $v_i$ is matched by alignment with the corresponding position of $S_{B^*}$. Notice that the solution $B^*$ is well-defined, as each $B^*(\{v_i, v_j\})$, with $\{v_i, v_j\} \in E$, can belong to an I-configuration of at most one of $B^*(v_i)$ and $B^*(v_j)$, since at most one of $v_i, v_j$ belongs to $I$.

Now, consider a longest common subsequence $S$ of $A$ and $B^*$. $S$ matches $4(m + n - 1)$ positions in substrings $S_{A,1}, \ldots, S_{A,m+n-1}$, since all the positions of these substrings are matched and, by construction, the overall length of $S_{A,1}, \ldots, S_{A,m+n-1}$ is $4(m + n - 1)$. Moreover, by definition of I-configuration and C-configuration, for each $v_i \in I$, $S$ matches $4|I| + 2$ positions of $A(v_i)$ and $2$ positions of each $A(\{v_i, v_j\})$, with $\{v_i, v_j\} \in E$; for each $v_i \in V \setminus I$, $S$ matches $5$ positions of $A(v_i)$; for each $\{v_i, v_j\} \in E$, with $v_i, v_j \in V \setminus I$, $S$ matches one position of $A(\{v_i, v_j\})$. Hence, $S$ matches $4(m + n - 1) + 6|I| + 5(n - |I|) + m$ positions of $A$ and $B^*$.

Based on Lemma 3, we can prove the following result.

**Lemma 5.** Let $G$ be a cubic graph, instance of Max-ISC, and let $(A,B,M)$ be the corresponding instance of $2\text{-LFCS}$. Then, given a solution $B^*$ of $2\text{-LFCS}$ over instance $(A,B,M)$ of length $4(m + n - 1) + 6p + 5(n - p) + m$, we can compute in polynomial time an independent set of $G$ of size at least $p$.

By Lemmata 4 and 5, and by the APX-hardness of Max-ISC [2] we can conclude that the $2\text{-LFCS}$ problem is APX-hard.

**Theorem 6.** $2\text{-LFCS}$ is APX-hard.

## 4 Approximating LFCS

In this section we give a polynomial-time approximation algorithm for LFCS of factor $\frac{3}{5}$. The approximation algorithm picks the largest number of matched positions returned by two polynomial-time algorithms, Approx-Algorithm-1 and Approx-Algorithm-2. Notice that each algorithm does not return a filling of $B$ with $M$, but two disjoint subsets of positions of $A$ that have to be matched by alignment and by insertion, respectively, by a subsequence of $A$ and of a filling of $B$ with $M$. We can easily compute in polynomial time a filling $B^*$ of $B$ with $M$ so that there exists a common subsequence of $A$ and $B^*$ that matches these two subsets of positions.

Both algorithms consist of two phases.

**Approx-Algorithm-1.** In the first phase, Approx-Algorithm-1 computes in polynomial time a longest common subsequence of $A$ and $B$. Denote by $R_{1,a}$ the positions of $A$ matched by alignment in the first phase and by $A'$ the subsequence of $A$ obtained by removing the positions of $R_{1,a}$. The second phase greedily computes in polynomial time a set $R_{1,i}$ of
The Longest Filled Common Subsequence Problem

OPT
Lemma 1, \(R_{2,i}\) is a set of positions of \(A\) of maximum cardinality that can be matched by insertion with symbols of \(M\), hence \(|R_{2,i}| \geq |OPT_i|\).

As a consequence of Lemma 7, it follows that \(|R_{1,a}| + |R_{2,i}| \geq |OPT_i| + |OPT_a| \geq |OPT|\). Hence the maximum of \(R_1, R_2\) is (at least) \(\frac{1}{2}|OPT|\). In the following, we show with a more refined analysis that the maximum of \(|R_1|, |R_2|\) is at least \(\frac{1}{2}|OPT|\).

We prove some bounds on \(R_{1,i}\) and \(R_{2,a}\), then we consider three cases depending on the values of \(OPT_{i,a}, OPT_{i,c}, OPT_{a,e}, OPT_{i,o}, OPT_{i,a,o}\) and \(OPT_{i,a,c}\). First, the following result holds.

\[\textbf{Lemma 8.} \] \(|R_{1,i}| \geq |OPT_{i,a}| + |OPT_{i,c}|\) and \(|R_{2,a}| \geq |OPT_{a,e}| + |OPT_{i,o}|\).

Now, in the analysis of the approximation factor of Approx-Algorithm-1 and Approx-Algorithm-2, we consider three cases, depending on the values of \(OPT_{i,c}, OPT_{i,a}, OPT_{i,a,c}\).

\[\textbf{Case 1} \]
Assume that \(|OPT_{i,c}| + |OPT_{i,a,c}| \geq \frac{1}{2}|OPT_{i,a}|\), we show the following result.

\[\textbf{Lemma 9.} \] Assume that \(|OPT_{i,c}| + |OPT_{i,a,c}| \geq \frac{1}{2}|OPT_{i,a}|\), then \(|R_1| \geq \frac{1}{2}|OPT|\).

\[\textbf{Proof.} \] Since \(|R_{1,i}| \geq |OPT_{i,a}| + |OPT_{i,c}|\) by Lemma 8, it follows that

\[|R_{1,a}| + |R_{1,i}| \geq |R_{1,a}| + |OPT_{i,a}| + |OPT_{i,c}| \geq \]

\[\frac{3}{5}(|R_{1,a}| + |OPT_{i,a}|) + \frac{2}{5}(|R_{1,i}| + |OPT_{i,c}|) + |OPT_{i,a,c}|.\]

By Lemma 7 it follows that \(|R_{1,a}| \geq |OPT_{a}|\) and, since \(|OPT_{a}| = |OPT_{a,o}| + |OPT_{a,c}|\), it follows that \(|R_{1,a}| \geq |OPT_{a,o}| + |OPT_{a,e}|\), hence

\[\frac{3}{5}(|R_{1,a}| + |OPT_{a,e}|) + \frac{2}{5}(|R_{1,a}| + |OPT_{a,c}|) + |OPT_{i,a,c}| \geq \]

\[\frac{3}{5}(|OPT_{a,o}| + |OPT_{a,e}| + |OPT_{i,c}|) + \frac{2}{5}(|R_{1,a}| + |OPT_{i,c}|) + |OPT_{i,a,c}|.\]

Hence, it holds

\[|R_{1,a}| + |R_{1,i}| \geq \frac{3}{5}(|OPT_{a,o}| + |OPT_{a,e}| + |OPT_{i,c}|) + \frac{2}{5}(|R_{1,a}| + |OPT_{i,c}|) + |OPT_{i,a,c}|.\] (1)

Notice that \(|R_{1,a}| + |OPT_{i,a,c}| \geq |OPT_{i,a,c}|\), since, by construction, each position in \(OPT_{i,a,c}\) is either in \(OPT_{i,a,c}\) or in \(R_{1,a}\). Then,

\[\frac{2}{5}(|R_{1,a}| + |OPT_{i,a,c}|) \geq \frac{2}{5}|OPT_{i,a,c}|.\] (2)

Since we are assuming that \(|OPT_{i,c}| + |OPT_{i,a,c}| \geq \frac{1}{2}|OPT_{i,a,c}|\), it holds

\[\frac{2}{5}(|OPT_{i,c}| + |OPT_{i,a,c}|) \geq \frac{1}{5}|OPT_{i,a,c}|.\] (3)

Combining Inequalities 2 and 3 with Inequality 1, we can conclude that, under the hypothesis \(|OPT_{i,c}| + |OPT_{i,a,c}| \geq \frac{1}{2}|OPT_{i,a,c}|\), it holds

\[|R_{1,a}| + |R_{1,i}| \geq \frac{3}{5}(|OPT_{a,o}| + |OPT_{a,e}| + |OPT_{i,c}|) + \frac{2}{5}(|R_{1,a}| + |OPT_{i,c}|) + |OPT_{i,a,c}| \geq \]

\[\frac{1}{2}|OPT|.|
The Longest Filled Common Subsequence Problem

\[
\frac{3}{5} (|OPT_{a,o}| + |OPT_{a,e}| + |OPT_{i,e}|) + \frac{2}{5} (|R_{1,a}| + |OPT'_{i,e}|) + \frac{2}{5} (|OPT_{i,e}| + |OPT''_{i,e}|) \geq \frac{3}{5} (|OPT_{a,o}| + |OPT_{a,e}| + |OPT_{i,o}| + |OPT_{i,e}|).
\]

It follows that, under the hypothesis \(|OPT_{i,e}| + |OPT''_{i,e}| \geq \frac{1}{2} |OPT_{i,o}|\), it holds \(|R_{1}| \geq \frac{3}{5} |OPT|\).

Case 2

Assume that \(|OPT_{a,e}| + |OPT'_{a,o}| \geq \frac{1}{2} |OPT_{a,o}|\). Similarly to Case 1, we can prove the following result.

▶ Lemma 10. Assume that \(|OPT_{a,e}| + |OPT'_{a,o}| \geq \frac{1}{2} |OPT_{a,o}|\), then \(|R_{2}| \geq \frac{3}{5} |OPT|\).

Case 3

Assume that both Case 1 and Case 2 do not hold. Then,

\[
|OPT_{i,e}| + |OPT'_{i,e}| < \frac{1}{2} |OPT_{i,o}| \quad \text{and} \quad |OPT_{a,e}| + |OPT'_{a,o}| < \frac{1}{2} |OPT_{a,o}|.
\]

Since \(|OPT_{i,e}| + |OPT'_{i,e}| < \frac{1}{2} |OPT_{i,o}|\), it follows that \(|OPT_{i,e}| < \frac{1}{2} |OPT_{i,o}|\) and, since \(|OPT_{a,e}| + |OPT'_{a,o}| < \frac{1}{2} |OPT_{a,o}|\), it follows that \(|OPT_{a,e}| < \frac{1}{2} |OPT_{a,o}|\). But then, since \(|OPT| = |OPT_{a,o}| + |OPT_{i,o}| + |OPT_{a,e}| + |OPT_{i,e}|\), it follows that

\[
|OPT| \leq \frac{3}{2} (|OPT_{a,o}| + |OPT_{i,o}|).
\]

We show that \(|R_{1}| \geq |OPT_{a,o}| + |OPT_{i,o}|\), thus implying that \(|R_{1}| \geq \frac{3}{5} |OPT|\).

▶ Lemma 11. \(|R_{1,a} \cup R_{1,i} \geq |OPT_{a,o}| + |OPT_{i,o}|\).

By Lemma 11, \(|R_{1,a} \cup R_{1,i} \geq |OPT_{a,o}| + |OPT_{i,o}|\). Since in this case we have shown that \(|OPT| \leq \frac{3}{2} (|OPT_{a,o}| + |OPT_{i,o}|)\), it follows that \(|R_{1} = |R_{1,a} \cup R_{1,i} \geq \frac{3}{2} |OPT| \geq \frac{3}{5} |OPT|\).

From Lemma 9, Lemma 10 and Lemma 11, it follows the main result of this section.

▶ Theorem 12. Given an instance \((A,B,M)\) of \(LFCS\), the largest solution returned by Approx-Algorithm-1 and Approx-Algorithm-2 is an approximate solution of factor \(\frac{3}{5}\).

Proof. From Lemma 9, Lemma 10 and Lemma 11, it follows that \(\max(|R_{1}|, |R_{2}|) \geq \frac{3}{5} |OPT|\).

We can compute a filling \(B_{1}\) of \(B\) with \(M\) that matches at least \(|R_{1}|\) positions with \(A\) as follows: we consider the positions in \(R_{1,a}\) as matched by alignment, we insert symbols of \(M\) in \(B\) in order to match by insertion the positions in \(R_{1,i}\). It follows that a longest common subsequence of \(A\) and \(B_{1}\) matches at least \(|R_{1}|\) positions.

Similarly, we can compute a filling \(B_{2}\) of \(B\) with \(M\) that matches at least \(|R_{2}|\) positions of \(A\). We insert symbols of \(M\) in \(B\) so that the positions in \(R_{1,i}\) are matched by insertion. Consider the subsequence \(A''\) obtained after the removal of positions in \(R_{1,i}\); a longest common subsequence of \(A''\) and \(B\) matches at least \(|R_{2,a}|\) positions. It follows that a longest common subsequence of \(A\) and \(B_{2}\) matches at least \(|R_{2}|\) positions.
5 An FPT Algorithm

In this section, we present an FPT algorithm for $\mathcal{LFC}_S$ parameterized by the number $k$ of positions of $A$ matched by insertions. Notice that $k < |M|$. Here we assume that the input sequences $A$ and $B$ have been extended by adding two symbols $\$A, $\$B \notin \Sigma$, respectively, in position 0 of $A$ and $B$, respectively. Hence we assume that position 0 of $A$ and of a filling $B^*$ of $B$ with $M$ is not matched by alignment or by insertion by any solution of $\mathcal{LFC}_S$ of length greater than zero.

The algorithm we present is based on the color-coding technique \cite{3}. Next, we present the definition of perfect families of hash functions for a multiset of symbols, on which our color-coding approach is based.

Definition 13. Let $M$ be a multiset of positions and let $F$ be a family of hash functions from $M$ to a set $\{c_1, \ldots, c_k\}$ of colors. $F$ is called perfect if for any subset $W \subseteq M$, such that $|W| = k$, there exists a function $f \in F$ which is injective on $W$.

A perfect family $F$ of hash functions from $M$ to $\{c_1, \ldots, c_k\}$, having size $O(\log |M| 2^{O(k)})$, can be constructed in time $O(2^{O(k)}|M| \log |M|)$ (see \cite{3}).

Consider a perfect family of hash functions $F : M \rightarrow \{c_1, \ldots, c_k\}$. Let $f \in F$ be an injective function, and define $L[i, j, C, l]$, with $C \subseteq \{c_1, \ldots, c_k\}$, $0 \leq i, l \leq |A|$ and $0 \leq j \leq |B|$, as follows:

- $L[i, j, C, l] = 1$ if and only if there exists a common subsequence of $A[0, i]$ and of a filling $B^*$ of $B[0, j]$ with $M$ having length $l$, such that there exist $|C|$ symbols of $M$ inserted in $B[0, j]$, each one associated with a distinct color of $C$ and matched by insertion with a position of $A$.
- else $L[i, j, C, l] = 0$.

Next, we define the recurrence to compute $L[i, j, C, l]$, where $i \geq 1$ and $j \geq 0$.

\[
L[i, j, C, l] = \begin{cases} 
L[i - 1, j, C, l] & \text{if } j \geq 1 \\
L[i, j - 1, C, l] & \text{if } A[i] = B[j] \text{ and } j \geq 1 \\
L[i - 1, j, C \setminus \{c\}, l - 1] & \text{if } A[i] = \alpha \text{ and there exists } \alpha \in M \text{ with } f(\alpha) = c \in C 
\end{cases}
\] (4)

For the base case, since we have extended $A$ and $B$ so that position 0 in $A$ and in the filling of $B$ cannot be matched by insertions or by alignment, it holds $L[0, 0, C, l] = 1$, if $C = \emptyset$ and $l = 0$, else $L[0, 0, C, l] = 0$. Next, we prove the correctness of the recurrence.

Lemma 14. Let $F : M \rightarrow \{c_1, \ldots, c_k\}$ be a perfect family of hash functions, let $f \in F$ be an injective function and let $C$ be a subset of $\{c_1, \ldots, c_k\}$. Then there exists a common subsequence of length $l$, $l \geq 0$, of $A[0, i]$, $0 \leq i \leq |A|$, and of a filling of $B[0, j]$, $0 \leq j \leq |B|$, with $M' \subseteq M$ such that each symbol of $M'$ matched by insertion is associated with a distinct color in $C$ if and only if $L[i, j, C, l] = 1$.

Now, we are able to prove the main result of this section.

Theorem 15. Let $A$, $B$ be two sequences and $M$ a multiset of symbols. Then it is possible to compute in time $2^{O(k)} \text{poly}(|A| + |B| + |M|)$ if there exists a solution $B^*$ of $\mathcal{LFC}_S$ over instance $(A, B, M)$ such that a longest common subsequence $S$ of $A$ and $B^*$ has length $l$ and it matches by insertion $k$ positions of $A$. 
14:12 The Longest Filled Common Subsequence Problem

Proof. The correctness of the algorithm follows from Lemma 14 and from the fact that entry \( L[|A|, |B|, C, l] = 1 \) if and only if there exists a solution of \( LFCS \) over instance \((A, B, \mathcal{M})\) having length \( l \) that matches by insertion \( k \) positions of \( A \).

Next, we consider the time complexity of the algorithm. A perfect family of hash functions that color-codes the symbols of \( \mathcal{M} \) can be computed in time \( 2^{O(k)} \text{poly}(|\mathcal{M}|) \). Then, the algorithm iterates through \( 2^{O(k)} \text{poly}(|\mathcal{M}|) \) color-codings. For each color-coding, the table \( L[i, j, C, l] \) is computed in time \( O(2^k |A|^2 |B| k) \) (where \( l \leq |A| \)), since for each of the at most \( O(2^k |A|^2 |B|) \) entries we need to look for at most \( k \) possible entries. The overall complexity is then \( 2^{O(k)} \text{poly}(|A| + |B| + |\mathcal{M}|) \).

\[\Box\]

6 Conclusion

We have introduced a variant of the LCS problem, called Longest Filled Common Subsequence (\( LFCS \)), to compare a sequence \( A \) with an incomplete sequence \( B \) to be filled with a multiset \( \mathcal{M} \) of symbols. We have shown that the problem is APX-hard (hence NP-hard), even when each symbol occurs at most twice in the input sequence \( A \). Then, we have given an approximation algorithm of factor \( \frac{3}{2} \) and a fixed-parameter algorithm, where the parameter is the number of symbols in \( \mathcal{M} \) matched by insertion.

There are some interesting open problems related to \( LFCS \). It would be interesting to extend \( LFCS \) to the comparison of two incomplete sequences, similar to what has been done for Scaffold Filling [15]. Moreover, it would be interesting to design more efficient parameterized algorithms for \( LFCS \), for example by considering the algebraic technique used for the repetition-free longest common subsequence [6]. Another open problem is whether \( LFCS \) is NP-hard on a constant size alphabet.

Abstract

We present new algorithms for the sliding window Lempel-Ziv (LZ77) problem and the approximate rightmost LZ77 parsing problem.

Our main result is a new and surprisingly simple algorithm that computes the sliding window LZ77 parse in \(O(w)\) space and either \(O(n)\) expected time or \(O(n \log \log w + z \log \log \sigma)\) deterministic time. Here, \(w\) is the window size, \(n\) is the size of the input string, \(z\) is the number of phrases in the parse, and \(\sigma\) is the size of the alphabet. This matches the space and time bounds of previous results while removing constant size restrictions on the alphabet size.

To achieve our result, we combine a simple modification and augmentation of the suffix tree with periodicity properties of sliding windows. We also apply this new technique to obtain an algorithm for the approximate rightmost LZ77 problem that uses \(O(n (\log z + \log \log n))\) time and \(O(n)\) space and produces a \((1 + \epsilon)\)-approximation of the rightmost parsing (any constant \(\epsilon > 0\)). While this does not improve the best known time-space trade-offs for exact rightmost parsing, our algorithm is significantly simpler and exposes a direct connection between sliding window parsing and the approximate rightmost matching problem.

Keywords and phrases Lempel-Ziv parsing, sliding window, rightmost matching

Digital Object Identifier 10.4230/LIPIcs.CPM.2017.15

1 Introduction

The Lempel-Ziv parsing (LZ77) \([36]\) of a string is a key component in data compression, detecting regularities in strings, pattern matching, and string indexing. LZ77 is the basis for several popular compression tools such as gzip and 7zip, and is shown to compress well under certain measures of compressibility \([21]\).

In general terms, given an input string \(S\) of length \(n\), the LZ77 parsing divides \(S\) into \(z\) substrings \(f_1 f_2 \ldots f_z\), called phrases, in a greedy left-to-right order. The \(i\)th phrase \(f_i\)

\(^{1}\) Supported by the Danish Research Council (DFF – 4005-00267, DFF – 1323-00178).
\(^{2}\) Supported by the Danish Research Council (DFF – 4005-00267).
\(^{3}\) Supported by the Danish Research Council (DFF – 4005-00267, DFF – 1323-00178).
starting at position \( p_i \) is either (a) the first occurrence of a character in \( S \) or (b) the longest substring that has at least one occurrence starting to the left of \( p_i \). To compress \( S \), we can then replace each phrase \( f_i \) of type (b) with a pair \((r_i, l_i)\) such that \( r_i \) is the distance from \( p_i \) to the start of the previous occurrence, and \( l_i \) is the length of the previous occurrence. (This is actually the LZ77-variant of Storer and Szymanski [33]; the original one [36] adds a character to each phrase so that it outputs triples instead of tuples.)

Computing the LZ77 parse is a very well-studied problem. The simplest way to compute the parse is to build an index for the input string, and scan the string left-to-right looking for the longest prefix of the current suffix occurring to the left of the current position. Using a suffix tree to index the string this yields \( O(n) \) time and space algorithm. Research on LZ77 parsing algorithms has since branched into practical and space-efficient computation [4, 12, 14, 16, 17, 19, 20, 22, 27, 30], parallel [31] and external computation [18], online parsing [28, 29, 32, 35], approximation of the parse [10], and algorithms that find the rightmost occurrence of a phrase [1, 8].

Almost all of the existing algorithms maintain an index of the entire input string, whereas almost all practical solutions only maintain a short window of length \( w \), for some parameter \( w \). of the input string near the current position in the string. This produces a sliding window LZ77 parse [2, 33] that has the property that a previous occurrence of a phrase starts no longer than \( w \) characters away from the current position. This limits the number of potential longest matches of a phrase to at most \( w \) and also reduces the number of bits needed to encode the reference to \( f_i \). Our main result is a new technique for indexing a sliding window. Using the technique we obtain an algorithm for LZ77 sliding window parsing that improves the previous best known time and space bounds for integer alphabets (and matches the known bounds for constant alphabets). The algorithm is surprisingly simple.

We then turn our heads to rightmost LZ77 parsing. The greedy LZ77 parse is optimal in terms of the number of phrases [6]. However, if we use variable length encoding of the phrases we may reduce the number of bits needed to encode each phrase. By choosing to reference the rightmost occurrence for each phrase we minimize the number of bits needed to encode the greedy LZ77 parse. Though several efficient algorithms for computing the rightmost parse are known, most require highly non-trivial algorithmic techniques. As an interesting application of our technique for sliding window LZ77 parsing, we obtain a very simple efficient approximate rightmost parsing algorithm. Interestingly, this algorithm exposes a direct connection between sliding window parsing and the approximate rightmost matching problem.

In the remainder of this section we will formally state the problems, our results, and discuss previous work.

1.1 Sliding Window Parsing

Given a parameter \( w \), the sliding window LZ77 parse (SWLZ77) of a string \( S \) is the LZ77 parse with the added requirement that the previous occurrence of a phrase \( f_i \) starts within distance at most \( w \) from the start of \( f_i \). To limit memory consumption, the SWLZ77 parse is used in most compression tools based on LZ77 in practice.

Fiala and Greene [9] and Larsson [24] show how to efficiently maintain the suffix tree of a sliding window of size \( w \). This immediately leads to an algorithm for computing the SWLZ77 parse in \( O(n) \) time and \( O(w) \) space. However, the algorithms are based on McCreight’s [25] and Ukkonen’s [34] suffix algorithms, respectively, and thus assume that the size of the alphabet is constant. (The same restriction on the alphabet size holds for the \( w \)-truncated suffix tree by Na et al. [26].) Furthermore, the algorithms require non-trivial modifications of
the classic suffix tree algorithms and are thus quite complicated. In practice, a hash table is used for strings in the dictionary, often sacrificing optimality for speed (see e.g. [23] for a survey on this).

In this paper we show the following result.

\textbf{Theorem 1.} Let \( S \) be a string of length \( n \) over an alphabet of size \( \sigma \). Given a parameter \( w \), we can compute the sliding window Lempel-Ziv parse in

(i) \( O(w) \) space and \( O(n) \) expected time, or
(ii) \( O(w) \) space and \( O(\frac{w}{\log \log \sigma}) + z \log \log \sigma \) deterministic worst-case time.

Here, \( z \) is number of phrases in the parsing, and \( \text{sort}(w, \sigma) \) is the time for sorting \( w \) characters from an alphabet of size \( \sigma \).

Hence, compared to the previous bounds, Theorem 1(i) matches the previous space bounds while achieving linear expected time and with no restrictions on the alphabet size. If we require a deterministic bound, Theorem 1(ii) incurs a small overhead. Plugging in the currently fastest deterministic sorting algorithm [15], which uses \( O(w \log \log w) \) time to sort \( w \) characters from an arbitrary alphabet, the bound becomes \( O(n \log \log w + z \log \log \sigma) \). We note that the additive overhead of \( O(z \log \log \sigma) \) is \( O(n) \) for most combinations of \( \sigma, n \), and \( z \).

The main technical challenges in the result are restricting the search for a previous occurrence to a dynamic window and supporting searches for self-referential phrases of length > \( w \) in \( O(w) \) space. To achieve this, we present a simple modification and augmentation of suffix trees, which we call \( w \)-sliding window trees, that supports linear time searching within a window and show how to exploit periodicity properties of windows to compactly search for long phrases in \( O(w) \) space. However, any text indexing data structure that supports basic suffix tree navigation operation can replace the \( w \)-sliding window tree in our solution if different time-space trade-offs are required.

1.2 Approximate Rightmost Parsing

Let \( \hat{r}_i \) denote the smallest possible choice of reference \( r_i \), i.e., \( \hat{r}_i \) is the distance to rightmost substring matching \( p_i \) that begins before \( p_i \) in \( S \). If \( r_i = \hat{r}_i \), \( i = 1, \ldots, z \) the parsing is rightmost and if \( \hat{r}_i \leq r_i \leq c \cdot \hat{r}_i \) for some \( c > 1 \) the parsing is \( c \)-rightmost. The rightmost parsing problem is to compute the rightmost parsing, and the approximate rightmost parsing problem is to compute a \( c \)-rightmost parsing for some \( c > 1 \).

Ferragina et al. [8] present an algorithm for the rightmost parsing problem with running time \( O(n(1 + \frac{\log \sigma}{\log \log n})) \) and using \( O(n) \) space. Recently, this was improved to \( O(n(1 + \frac{\log \sigma}{\sqrt{\log n}})) \) time and \( O(n \log \sigma) \) bits of space by Belazzougui and Puglisi [1]. Prior to these results, Crochemore et al. [5] presented, to the best of our knowledge, the only approximate rightmost parsing algorithm. Their algorithm runs in \( O(n \log n) \) time and \( O(n) \) space and it finds the rightmost equal-cost position (REP) for each phrase in the greedy LZ77 parse. The REP for a phrase \( f_i \) is some occurrence for which \( r_i \) requires the same number of bits to encode as \( \hat{r}_i \). If \( \hat{r}_i \) is a power of 2 the algorithm finds an occurrence where \( r_i \leq 2\hat{r}_i - 1 \), i.e., roughly speaking their algorithm is producing a 2-rightmost parsing.

All of the above solutions require several highly non-trivial components to achieve their bounds. We show how our solution to the Lempel-Ziv sliding window problem immediately leads to an efficient approximate rightmost parsing algorithm summarized in the following theorem.
Lempel-Ziv Compression in a Sliding Window

Figure 1 (a) The $w$-sliding window tree for window size $w = 8$. Text positions at the leaves are relative to the end $e$ of the previous sliding window, implying they must be incremented by $e$ to get absolute positions. (b) Parsing with $w$-sliding window trees $T$ and $T'$ for blocks $b$ and $b'$.

Theorem 2. Let $S$ be a string of length $n$. For any $\varepsilon > 0$ we can compute a $(1 + \varepsilon)$-rightmost Lempel-Ziv parsing in $O(n \log z + n \log \log n)$ time and $O(n)$ space, where $z$ is the number of phrases in the parse.

While our result does not improve the best known trade-offs for rightmost parsing, the algorithm is significantly simpler. It applies our new technique of combining $w$-sliding window trees and periodicity properties and thereby exposes a direct connection between sliding windows and approximate rightmost matching problems.

2 Lempel-Ziv in a Sliding Window

We now show Theorem 1. Throughout the paper, let $S$ be a string of length $n$ over an alphabet of size $\sigma$. We partition $S$ into blocks of size $w$ and parse $S$ from left to right. For these blocks we store a special suffix tree, which we call a $w$-sliding window tree.

Definition 3 (The $w$-sliding window tree). The $w$-sliding window tree of a block is the compact trie of all length $w$ strings starting in the block. Each leaf stores all starting positions of the substring it represents. For each edge $e$ in the $w$-sliding window trees we store the minimum starting position, $\text{min}(e)$, and the maximum starting position, $\text{max}(e)$, stored in all leaves below it. The $w$-sliding window tree at position $i$ is the $w$-sliding window tree for the block starting at position $i$.

See Figure 1(a) for an example of a $w$-sliding window tree. We have that the $w$-sliding window uses $O(w)$ space. Also, given the suffix tree of the string of length $2w$ starting at position $i$, we can easily build $w$-sliding window tree starting at position $i$ in $O(w)$ time by truncating all suffixes to length $w$.

While showing Theorem 1 in the following sections, we will also show the following Lemma that we will need for our approximate rightmost matching algorithm. Given two indices $i$ and $j$ in $S$, let $\text{lep}(i,j)$ denote the length of the longest common prefix of $S[i,n]$ and $S[j,n]$.

Lemma 4. Given two $w$-sliding window trees at position $x$ and $x + w$, respectively, we can find $\ell = \max_{i-w \leq j < i} \text{lep}(i,j)$ for any $i \in [x+w, x+2w)$ in $O(\ell)$ time (assuming the suffix-trees support constant-time top-down-traversals).
For simplicity, we first consider the case where the length of each phrase is at most $w$, and then extend the result to handle arbitrary length phrases.

2.1 Bounded Phrase Length

We first show how to find longest matches if the length of each phrase is at most $w$. We partition $S$ into blocks of size $w$ and parse $S$ from left-to-right. We only maintain the last two blocks in memory.

2.1.1 Parsing

We implement the sliding window parsing using the $w$-sliding window trees as follows. See also Figure 1(b). Suppose we have parsed the first $i - 1$ characters of $S$ and currently have the $w$-sliding window trees $T$ and $T'$ for the last two blocks $b$ and $b'$ stored. To compute the phrase starting at position $i$, we traverse $T$ and $T'$ top-down according to the substring starting at position $i$. In $T$, we compare $i$ to max($e$) each time we follow edge $e$. If max($e$) is within the window (if max($e$) ≥ $i - w$) we continue the search and otherwise we stop the search. If we reach a leaf we also stop. When the search stops, we output max($e$) of the previous edge $e$ as the starting position of the longest match in $T$. In $T'$ we compare with min($e$) in the same fashion. That is, we only continue the search if min($e$) is smaller than $i$. We output min($e$) of the previous edge $e$ as the starting position of the longest match in $T'$. We return the maximum of the longest matching path found in $T$ and $T'$ as the longest matching substring within the window.

2.1.2 Correctness

We argue that the algorithm correctly finds a longest match. A longest match within the window must start in one of the two blocks $b$ or $b'$. Since we only continue the search in $T$ as long as max($e$) is in the window, the match that we found starts at a position in the window. Similarly for $T'$.

2.2 Unbounded Phrase Length

We now consider the general case of unbounded phrase length and show how to extend the solution from the previous section to handle this case by exploiting a periodicity property of the sliding window [3].

Given a $w$-sliding window tree we now might reach a leaf, from where we need to continue the matching further. If there is only one substring stored at the leaf we can simply continue matching the corresponding substrings in $S$ until the phrase ends. Unfortunately, we may have multiple strings stored at a leaf and thus we cannot afford naively matching against these.

We modify searching for longest match starting at position $i$ as follows. We match in the $w$-sliding window trees $T$ and $T'$ just as before. If we reach a leaf in $T$ we pick the maximum starting position $x$ stored in the leaf ($x = \text{max}(e)$ if $e$ is the incoming edge) and continue matching from position $i + w$ and $x + w$ until we get a mismatch. If we reach a leaf in $T'$ we pick the minimum starting position stored in the leaf (using min($e$)) and continue matching in the same fashion.
2.2.1 Correctness and Analysis

To show that the modification works correctly we will show the following. Let \( f_i \) be a phrase of length \( > w \) starting at position \( p_i \). If there are multiple strings in the \( w \)-sliding window tree that start in the window \( S[p_i - w, p_i - 1] \) and match the first \( w \) characters of \( f_i \), then all of these strings can be extended to longest matches with \( f_i \). In particular, since the algorithm chooses one of these string to compare against (the maximum or minimum such string) this implies that the algorithm is correct.

We need the following lemma.

\[ \textbf{Lemma 5} \] (Breslauer and Galil [3], Lemma 3.1). Let \( P \) and \( S \) be strings such that \( S \) contains at least three occurrences of \( P \). Let \( t_1 < t_2 < \cdots < t_h \) be the locations of all occurrences of \( P \) in \( S \) and assume that \( t_{i+2} - t_i \leq |P| \), for \( i = 1, \ldots, h - 2 \) and \( h \geq 3 \). Then, this sequence forms an arithmetic progression with difference \( d = t_{i+1} - t_i \), for \( i = 1, \ldots, h - 1 \), that is equal to the period length of \( P \).

Using Lemma 5 we show the following result.

\[ \textbf{Lemma 6}. \] Assume we reach a leaf in the \( w \)-sliding window tree \( T \) (or \( T' \)) when matching the phrase starting at \( p_i \), and that there are \( k \geq 2 \) strings that are associated with the leaf and start in the window \( S[p_i - w, p_i - 1] \). Let \( t_1 < \cdots < t_k \) be the starting positions of the strings. Then \( \text{lcp}(p_i, t_j) = l_i \) for all \( j = 1, \ldots, k \).

\[ \textbf{Proof}. \] The starting positions \( t_1, \ldots, t_k \) correspond to starting positions of occurrences of the \( w \)-length substring \( S[p_i, p_i + w - 1] \). Since they all start in the window \( S[p_i - w, p_i - 1] \) we have \( p_i - w \leq t_j < p_i \) for all \( j = 1, \ldots, k \). Therefore \( t_{j+2} - t_j \leq w \) for all \( 1 \leq j \leq k - 2 \) and also \( p_i - t_{k-1} \leq w \), and it follows from Lemma 5 that the sequence \( t_1, t_2, \ldots, t_k, p_i \) forms an arithmetic progression, i.e., the substring \( S[p_i, p_i + w - 1] \) is periodic with period length \( d = p_i - t_k \). The suffix \( S[p_i, n] \) starts with \( r \geq 1 \) whole repetitions of the period followed by possibly a prefix of the period of length \( r' < d \). Let \( l_i = rd + r' \). All the suffixes \( S[t_1, n], \ldots, S[t_k, n] \) start with strictly more than \( r \) repetitions of the period. Therefore, they all match with \( S[p_i, n] \) up to position \( p_i + l_i - 1 \). Thus, continuing matching from any of these when we reach the leaf in \( T \) will give us the correct answer. The proof for the case where we reach a leaf in \( T' \) is similar. \[ \square \]

In summary, this proves that the algorithm finds the longest match and thus correctly computes the SWLZ77 parse.

2.3 Implementation and Analysis

The total space for the two \( w \)-sliding window trees stored at any time is \( O(w) \). Building the \( w \)-sliding window trees requires building a suffix tree of size \( 2w \). If the alphabet size is polynomial \( (\sigma = n^{O(1)}) \) we can build all \( [n/w] \) suffix trees in total \( O(n) \) worst-case time [7]. If the alphabet size is larger we first hash to a polynomial sized alphabet and then build the suffix trees. This takes \( O(n) \) expected time. Given the suffix tree for a \( 2w \) length substring we construct the \( w \)-sliding window tree in \( O(w) \) time and use perfect hashing at each node [13] to index the first characters of outgoing edges and thus enable linear time matching (building the perfect hash tables takes expected \( O(w) \) time). This concludes the proof of Lemma 4.

In total we get \( O(n) \) expected time for constructing all \( w \)-sliding window trees, and \( O(n) \) time for searching for all phrases. This sums to \( O(n) \) expected time as desired. This proves Theorem 1(i).
To get deterministic bounds of Theorem 1(ii), we can instead build the suffix trees using Fischer and Gawrychowski [11]. These build suffix trees in sorting time complexity and support searches for a pattern of length $m$ in $O(m + \log \log \sigma)$ time. We search for $z$ phrases of total length $n$, and hence in total we use $O\left(\frac{w}{m}\text{sort}(w, \sigma) + z \log \log \sigma\right)$ time. In summary, this proves Theorem 1.

3 Approximate Rightmost Matching

We now show Theorem 2.

3.1 Algorithm

We assume that we have the leftmost LZ77 parse (defined analogously to the rightmost parse, see beginning of Section 1.2) of the input string. If not we can easily compute it within the bounds of Theorem 2. Our algorithm updates the references of the phrases in a left-to-right order.

For levels $i = 1, \ldots, \log (1+\epsilon)n$ we build the $w$-sliding window trees for $S[j(1+\epsilon)^i, (j+1)(1+\epsilon)^i]$ for $j = 0, \ldots, \left\lfloor \frac{n}{(1+\epsilon)^i} \right\rfloor - 1$. That is, for a fixed $i$, we compute all the $w$-sliding window trees of size $(1+\epsilon)^i$ spaced by $(1+\epsilon)^i$ characters (remember $\epsilon > 0$ is an arbitrary constant).

Definition 7 (Covering $w$-sliding window tree). Given a position $k$ in $S$ such that $j(1+\epsilon)^i \leq k \leq (j+1)(1+\epsilon)^i$ for some $i$ and $j$, we say that the $w$-sliding window tree of the substring $S[j(1+\epsilon)^i, (j+1)(1+\epsilon)^i]$ is covering $k$ on level $i$. We denote this tree by $T_{i,k}$.

We maintain references to the $w$-sliding window trees such that given $k$ and $i$ we can find the $w$-sliding window tree on level $i$ covering $k$ in constant time.

To update a reference of a phrase $f_l$ beginning at position $p_l$ to be the $(1+\epsilon)$-rightmost, we search the $w$-sliding window trees $T_{i,p_l-(1+\epsilon)^i}$ and $T_{i,p_l}, i = 1, \ldots, \log (1+\epsilon)n$, for the occurrence of $f_l$ closest to (but not after) $p_l$. We then update the phrase $f_l$. The search is done as described in Lemma 4.

The order in which the $w$-sliding window trees are searched is a binary search over the levels. If an occurrence is found at level $i$ we continue the search on the smaller levels. If not, we continue the search on the bigger levels.

We assumed that all $w$-sliding window trees were built as the first step of the algorithm, but we can restrict the algorithm to only build the $w$-sliding window trees that are in fact needed and then discard them again when the algorithm progresses to a position not covered by it. In the proof of Theorem 2 we show that this improves the total time used to construct the $w$-sliding window trees from $O(n \log n)$ to $O(n \log z)$ and the space usage to $O(n)$.

3.2 Analysis

In this section we prove Theorem 2. We start by showing the approximation guarantees of our algorithm and then we analyze its space and time complexity.

3.2.1 Approximation

Here we prove that our algorithm produces a $(1+\epsilon)$-rightmost parsing.

Lemma 8. Let $f_1, \ldots, f_z = (r_1, l_1), \ldots, (r_z, l_z)$ be the parsing produced by our algorithm. For $k = 1, \ldots, z$ we have that $r_k \leq (1+\epsilon)\hat{r}_k$, i.e., our algorithm produces a $(1+\epsilon)$-rightmost parsing.
The space used by our algorithm is dominated by the \( w \)-sliding window trees we construct. Once we are done using a \( w \)-sliding window tree we can discard it. When processing \( f_1 \) we only need the \( w \)-sliding window trees covering \( p_i \) and \( p_i - (1+\epsilon)^i \) for every level \( i \). So at any point in time the total size of the maintained \( w \)-sliding window trees is bounded by \( \sum_{i=1}^{\log_1 w} n O((1+\epsilon)^i) = O(n) \), hence the space usage by our algorithm is \( O(n) \).

### Time

First we analyze the time required for constructing the \( w \)-sliding window trees. Recall that a suffix tree is only constructed if we actually need to access it. For each phrase beginning we may have to access \( \log_1 w \) \( w \)-sliding window trees, however some of these may be reused. Our algorithm parses the string left to right, so if a \( w \)-sliding window tree is covering both \( p_i \) and \( p_{i+1} \) we only need to construct it once since we process \( f_{i+1} \) immediately after \( f_i \).

In the worst case, we may be required to build all \( w \)-sliding window trees on level \( \log_1 w \) \( n - \log_1 w \) \( z \), meaning that all possible \( w \)-sliding window trees on level \( 1 + \log_1 w \) \( n - \log_1 w \) \( z \) to \( \log_1 w \) \( n \) will also have to be built. This requires \( O(n \log z) \) time since the total size of the \( w \)-sliding window trees on any level is \( O(n) \) and the number of levels is \( \log_1 w \) \( z \).

In the worst case the \( w \)-sliding window trees on the remaining levels are not subject to reuse. On level \( \log_1 w \) \( n - \log_1 w \) \( z \) the total size of the \( w \)-sliding window trees is \( O(n) \). On the previous level we also need to build at most \( z \) \( w \)-sliding window trees but the total size of these will be \( O(n/(1+\epsilon)) \). Therefore the total size of the \( w \)-sliding window trees on the
lower levels is at most $\sum_{i=1}^{\log_1(1+\epsilon)n} 2^{-i} \frac{n}{1+i} = O(n)$. The total time for building the the $w$-sliding window trees is thus $O(n \log z + n) = O(n \log z)$ time. See also Figure 2.

We now look at the time it takes to search the $w$-sliding window trees. Consider phrase $f_l$ and assume that we have all the $w$-sliding window trees covering $p_l$. We binary search for the $w$-sliding window tree having an occurrence of $f_l$ as close to $p_l$ as possible. Since there are $\log_1(1+\epsilon)n$ levels this takes $O(|f_l| \log \log n)$ time, resulting in a total of $\sum_{i=1}^{\log_1(1+\epsilon)n} |f_i| \log \log n = O(n \log \log n)$ time for this step. In total our algorithm uses $O(n \log z + \log \log n)$ time.

This concludes the proof of Theorem 2.

Abstract

Given a string $S$, the \textit{compressed indexing problem} is to preprocess $S$ into a compressed representation that supports fast substring queries. The goal is to use little space relative to the compressed size of $S$ while supporting fast queries. We present a compressed index based on the Lempel-Ziv 1977 compression scheme. Let $n$, and $z$ denote the size of the input string, and the compressed LZ77 string, respectively. We obtain the following time-space trade-offs. Given a pattern string $P$ of length $m$, we can solve the problem in

(i) $O(m + \text{occ lg} n)$ time using $O(z \text{lg} (n/z) \text{lg} z)$ space, or

(ii) $O(m(1 + \frac{\text{occ \lg} n}{\text{lg} (n/z)}) + \text{occ} (\text{lg} n + \lg^2 z))$ time using $O(z \text{lg} (n/z))$ space, for any $0 < \epsilon < 1$

In particular, (i) improves the leading term in the query time of the previous best solution from $O(m \text{lg} m)$ to $O(m)$ at the cost of increasing the space by a factor $\lg \text{lg} z$. Alternatively, (ii) matches the previous best space bound, but has a leading term in the query time of $O(m(1 + \frac{\text{lg}^2 z}{\text{lg} (n/z)})$. However, for any polynomial compression ratio, i.e., $z = O(n^{1-\delta})$, for constant $\delta > 0$, this becomes $O(m)$. Our index also supports extraction of any substring of length $\ell$ in $O(\ell + \text{lg} (n/z))$ time. Technically, our results are obtained by novel extensions and combinations of existing data structures of independent interest, including a new batched variant of weak prefix search.

1 Introduction

Given a string $S$, the \textit{compressed indexing problem} is to preprocess $S$ into a compressed representation that supports fast substring queries, that is, given a string $P$, report all occurrences of substrings in $S$ that match $P$. Here the compressed representation can be any
compression scheme or measure (kth order entropy, smallest grammar, Lempel-Ziv, etc.). The goal is to use little space relative to the compressed size of S while supporting fast queries. Compressed indexing is a key computational primitive for querying massive data sets and the area has received significant attention over the last decades with numerous theoretical and practical solutions, see e.g. [25, 12, 29, 13, 14, 21, 22, 15, 34, 30, 9, 27, 18, 24, 4] and the surveys [34, 32, 33, 19].

The Lempel-Ziv 1977 compression scheme (LZ77) [37] is a classic compression scheme based on replacing repetitions by references in a greedy left-to-right order. Numerous variants of LZ77 have been developed and several widely used implementations are available (such as gzip [20]). Recently, LZ77 has been shown to be particularly effective at handling highly-repetitive data sets [30, 32, 27, 8, 3] and LZ77 compression is always at least as powerful as any grammar representation [36, 7].

In this paper, we consider compressed indexing based on LZ77 compression. Relatively few results are known for this version of the problem. Let n, z, and m denote the size of the input string, the compressed LZ77 string, and the pattern string, respectively. Kärkkäinen and Ukkonen introduced the problem in 1996 [25] and gave an initial solution that required read-only access to the uncompressed text. Interestingly, this work is among the first results in compressed indexing [34]. More recently, Gagie et al. [17, 18] revisited the problem and gave a solution using space $O(z \lg(n/z))$ and query time $O(m \lg m + \text{occ} \lg \lg n)$, where occ is the number of occurrences of P in S. Note that these bounds assume a constant sized alphabet.

### 1.1 Our Results

We show the following main result.

- **Theorem 1.** Given a string $S$ of length $n$ from a constant sized alphabet compressed using LZ77 into a string of length $z$ we can build a compressed-index supporting substring queries in:
  
  1. $O(m + \text{occ} \lg \lg n)$ time using $O(z \lg(n/z) \lg \lg z)$ space, or
  2. $O(m(1 + \frac{\lg z}{\lg(n/z)}) + \text{occ}(\lg \lg n + \lg \beta z))$ time using $O(z \lg(n/z))$ space, for any $0 < \epsilon < 1$

Compared to the previous bounds Theorem 1 obtains new interesting trade-offs. In particular, Theorem 1 (i) improves the leading term in the query time of the previous best solution from $O(m \lg m)$ to $O(m)$ at the cost of increasing the space by only a factor $\lg \lg z$. Alternatively, Theorem 1 (ii) matches the previous best space bound, but has a leading term in the query time of $O(m(1 + \frac{\lg z}{\lg(n/z)}))$. However, for any polynomial compression ratio, i.e., $z = O(n^{1-\delta})$, for constant $\delta > 0$, this becomes $O(m)$.

Gagie et al. [18] also showed how to extract an arbitrary substring of $S$ of length $\ell$ in time $O(\ell + \lg n)$. We show how to support the same extraction operation and slightly improve the time to $O(\ell + \lg(n/z))$.

Technically, our results are obtained by new variants and extensions of existing data structures in novel combinations. In particular, we consider a batched variant of the weak prefix search problem and give the first non-trivial solution to it. We also generalize the well-known bidirectional compact trie search technique [28] to reduce the number of queries at the cost of increasing space. Finally, we show how to combine this efficiently with range reporting and fast random-access in a balanced grammar leading to the result.

As mentioned all of the above bounds hold for a constant size alphabet. However, Theorem 1 is an instance of full time-space trade-off that also supports general alphabets. We discuss the details in Section 8 and Appendix 8.1.
2 Preliminaries

We assume a standard unit-cost RAM model with word size \( w = \Theta(\log n) \) and that the input is from an integer alphabet \( \Sigma = \{1, 2, \ldots, n^{O(1)}\} \) and measure space complexity in words unless otherwise specified.

A string \( S \) of length \( n = |S| \) is a sequence \( S[1] \ldots S[n] \) of \( n \) characters drawn from \( \Sigma \). The string \( S[i] \ldots S[j] \) denoted \( S[i, j] \) is called a substring of \( S \). \( \epsilon \) is the empty string and \( S[i, i] = S[i] \) while \( S[i, j] = \epsilon \) when \( i > j \). The substrings \( S[1, i] \) and \( S[j, n] \) are the \( i^{th} \) prefix and the \( j^{th} \) suffix of \( S \) respectively. The reverse of the string \( S \) is denoted \( \text{rev}(S) = S[n]S[n−1] \ldots S[1] \).

Let \( D \) be a set of \( k \) strings and let \( T_D \) be the compact trie storing all the strings of \( D \). \( \text{str}(v) \) denotes the prefix corresponding to the vertex \( v \). The depth of \( v \) is the number of edges on the path from \( v \) to the root. We assume each string in \( D \) is terminated by a special character \( \$ \notin \Sigma \) such that each string in \( D \) corresponds to a leaf. The children of each vertex are sorted from left to right in increasing lexicographical order, and therefore the left to right order of the leaves corresponds to the lexicographical order of the strings in \( D \). Let \( \text{rank}(s) \) denote the rank of the string \( s \in D \) in this order. The skip interval of a vertex \( v \in T_D \) with parent \( u \) is \( (|\text{str}(u)|, |\text{str}(v)|) \) denoted \( \text{skip}(v) \) and \( \text{skip}(v) = \emptyset \) if \( v \) is the root. The locus of a string \( s \) in \( T_D \), denoted \( \text{locus}(s) \), is the minimum depth vertex \( v \) such that \( s \) is a prefix of \( \text{str}(v) \). If there is no such vertex, then \( \text{locus}(s) = -1 \). In order to reduce the space used by \( T_D \) we only store the first character of every edge and in every vertex \( v \) we store \( |\text{str}(v)| \) (This variation is also known as a PATRICIA tree [31]). We navigate \( T_D \) by storing a dictionary in every internal vertex mapping the first character of the label of an edge to the respective child. The size of \( T_D \) is \( O(k) \).

A Karp-Rabin fingerprinting function [26] is a randomized hash function for strings. We use a variation of the original definition appearing in Porat and Porat [35]. The fingerprint for a string \( S \) of length \( n \) is defined as: \( \phi(S) = \sum_{i=1}^{n} S[i] \cdot r^{i−1} \mod p \), where \( p \) is a prime and \( r \) is a random integer in \( \mathbb{Z}_p \) (the field of integers modulo \( p \)). Storing the values \( n \), \( r^n \mod p \) and \( r^{n−1} \mod p \) along with a fingerprint allows for efficient composition an subtraction of fingerprints. Using this we can compute and store the fingerprints of each of the prefixes of a string \( S \) of length \( n \) in \( O(n) \) time and space such that we afterwards can compute the fingerprint of any substring \( S[i, j] \) in constant time. We say that the fingerprints of the strings \( x \) and \( y \) collide when \( \phi(x) = \phi(y) \) and \( x \neq y \). A fingerprinting function \( \phi \) is collision-free for a set of strings if there are no fingerprint collisions between any of the strings. Porat and Porat [35] show that if \( x \) and \( y \) are different strings of length at most \( n \) and \( p = \Theta(n^{2+\alpha}) \) for some \( \alpha > 0 \), then the probability that \( \phi(x) = \phi(y) \) is less than \( 1/n^{1+\alpha} \).

The LZ77 parse of a string \( S \) of length \( n \) is a sequence \( Z \) of \( z \) subsequent substrings of \( S \) called phrases such that \( S = Z[1]Z[2] \ldots Z[z] \). \( Z \) is constructed in a left to right pass of \( S \): Assume that we have found the sequence \( Z[1, i] \) producing the string \( S[1, j−1] \) and let \( S[j, j−1] \) be the longest prefix of \( S[j, n−1] \) that is also a substring of \( S[1, j−2] \). Then \( Z[i+1] = S[j, j−1] \). The occurrence of \( S[j, j−1] \) in \( S[1, j−2] \) is called the source of the phrase \( Z[i] \). Thus a phrase is composed by the contents of its possibly empty source and a trailing character which we call the phrase border and is typically represented as a triple \( Z[i] = \text{(start, len, c)} \) where \( \text{start} \) is the starting position of the source, \( \text{len} \) is the length of the source and \( c \in \Sigma \) is the border. For a phrase \( Z[i] = S[j, j] \) we denote the position of its border by \( \text{border}(Z[i]) = j \) and its source by \( \text{source}(Z[i]) = S[j, j−1] \). For example, the string \( aabc \ldots abc \) of length \( n \) has the LZ77 parse \( [a, b, c, a, b, c, \ldots a, b, c] \) of length \( 4 \) which is represented as \( Z = (0, 0, a)(0, 0, b)(0, 0, c)(0, n−4, c) \).
3 Prefix Search

The prefix search problem is to preprocess a set of strings such that later, we can find all the strings in the set that are prefixed by some query string. Belazzougui et al. [2] consider the weak prefix search problem, a relaxation of the prefix search problem where we are only requested to output the ranks (in lexicographic order) of the strings that are prefixed by the query pattern and we only require no false negatives. Thus we may answer arbitrarily when no strings are prefixed by the query pattern.

Lemma 2 (Belazzougui et al. [2], appendix H.3). Given a set $D$ of $k$ strings with average length $l$, from an alphabet of size $\sigma$, we can build a data structure using $O(k(lg l + lg lg \sigma))$ bits of space supporting weak prefix search for a pattern $P$ of length $m$ in $O(m lg \sigma/w + lg m)$ time where $w$ is the word size.

The term $m lg \sigma/w$ stems from preprocessing $P$ with an incremental hash function such that the hash of any substring $P[i, j]$ can be obtained in constant time afterwards. Therefore we can do weak prefix search for $h$ substrings of $P$ in $O(m lg \sigma/w + h lg m)$ time. We now describe a data structure that builds on the ideas from Lemma 2 but obtains the following:

Lemma 3. Given a set $D$ of $k$ strings, we can build a data structure taking $O(k)$ space supporting weak prefix search for $h$ substrings of a pattern $P$ of length $m$ in time $O(m + h(m/x + lg x))$ where $x$ is a positive integer.

If we know $h$ when building our data structure, we set $x$ to $h$ and obtain a query time of $O(m + h lg h)$ with Lemma 3.

Before describing our data structure we need the following definition: The 2-fattest number in a nonempty interval of strictly positive integers is the number in the interval whose binary representation has the highest number of trailing zeroes.

3.1 Data Structure

Let $T_D$ be the compact trie representing the set $D$ of $k$ strings and let $x$ be a positive integer. Denote by $fat(v)$ the 2-fattest number in the skip interval of a vertex $v \in T_D$. The fat prefix of $v$ is the length $fat(v)$ prefix of str($v$). Denote by $D^{fat}$ the set of fat prefixes induced by the vertices of $T_D$. The $x$-prefix of $v$ is the shortest prefix of str($v$) whose length is a multiple of $x$ and is in the interval $skip(v)$. If $v$‘s skip interval does not span a multiple of $x$, then $v$ has no $x$-prefix. Let $D^x$ be the set of $x$-prefixes induced by the vertices of $T_D$. The data structure is the compact trie $T_D$ augmented with:

- A fingerprinting function $\phi$.
- A dictionary $G$ mapping the fingerprints of the strings in $D^{fat}$ to their associated vertex.
- A dictionary $H$ mapping the fingerprints of the strings in $D^x$ to their associated vertex.
- For every vertex $v \in T_D$ we store the rank in $D$ of the string represented by the leftmost and rightmost leaf in the subtree of $v$, denoted $l_v$ and $r_v$, respectively.

The data structure is similar to the one by Belazzougui et al. [2] except for the dictionary $H$, which we use in the first step of our search. There are at most $k$ strings in each of $D^{fat}$ and $D^x$ thus the total space of the data structure is $O(k)$.

Let $i$ be the start of the skip interval of some vertex $v \in T_D$ and define the pseudo-fat numbers of $v$ to be the set of 2-fattest numbers in the intervals $[i, p]$ where $i \leq p < fat(v)$. We require that the fingerprinting function $\phi$ is collision-free for the strings in $D^{fat}$, the strings in $D^x$ and all the length $l$-prefixes of the strings in $D$ where $l$ is a pseudo-fat number in the skip interval of some vertex $v \in T_D$. 

Observe that the range of strings in $D$ that are prefixed by some pattern $P$ of length $m$ is exactly $[l_v, r_v]$ where $v = \text{locus}(P)$. Answering a weak prefix search query for $P$ is comprised by two independent steps. First step is to find a vertex $v \in T_D$ such that $\text{str}(v)$ is a prefix of $P$ and $m - |\text{str}(v)| \leq x$. We say that $v$ is in $x$-range of $P$. Next step is to apply a slightly modified version of the search technique from Belazzougui et al. [2] to find the exit vertex for $P$, that is, the deepest vertex $v' \in T_D$ such that $\text{str}(v')$ is a prefix of $P$. Having found the exit vertex we can find the locus in constant time as it is either the exit vertex itself or one of its children.

**Finding an x-range Vertex.** We now describe how to find a vertex in $x$-range of $P$. If $m < x$ we simply report that the root of $T_D$ is in $x$-range of $P$. Otherwise, let $v$ be the root of $T_D$ and for $i = 1, 2, \ldots, [m/x]$ we check if $ix > |\text{str}(v)|$ and $\phi(P[1, ix])$ is in $H$ in which case we update $v$ to be the corresponding vertex. Finally, if $|\text{str}(v)| \geq m$ we report that $v$ is locus($P$) and otherwise we report that $v$ is in $x$-range of $P$. In the former case, we report $[l_v, r_v]$ as the range of strings in $D$ prefixed by $P$. In the latter case we pass on $v$ to the next step of the algorithm.

We now show that the algorithm is correct when $P$ prefixes a string in $D$. It is easy to verify that the $x$-prefix of $v$ prefixes $P$ at all time during the execution of the algorithm. Assume that $|\text{str}(v)| \geq m$ by the end of the algorithm. We will show that in that case $v = \text{locus}(P)$, i.e., that $v$ is the highest node prefixed by $P$. Since $P$ prefixes a string in $D$, the $x$-prefix of $v$ prefixes $P$, and $|\text{str}(v)| \geq m$, then $P$ prefixes $v$. Since the $x$-prefix of $v$ prefixes $P$, $P$ does not prefix the parent of $v$ and thus $v$ is the highest node prefixed by $P$.

Assume now that $|\text{str}(v)| < m$. We will show that $v$ is in $x$-range of $P$. Since $P$ prefixes a string in $D$ and the $x$-prefix of $v$ prefixes $P$, then $\text{str}(v)$ prefixes $P$. Let $P[1, ix]$ be the $x$-prefix of $v$. Since $v$ is returned, either $\phi(P[1, jx]) \notin H$ or $jx \leq |\text{str}(v)|$ for all $i < j \leq [m/x]$. If $\phi(P[1, jx]) \notin H$ then $P[1, jx]$ is not a $x$-prefix of any node in $T_D$. Since $P$ prefixes a string in $D$ this implies that $jx$ is in the skip interval of $v$, i.e., $jx \leq |\text{str}(v)|$. This means that $jx \leq |\text{str}(v)|$ for all $i < j \leq [m/x]$. Therefore $|m/x| x \leq |\text{str}(v)| < m$ and it follows that $m - |\text{str}(v)| < x$. We already proved that $\text{str}(v)$ prefixes $P$ and therefore $v$ is in $x$-range of $P$.

In case $P$ does not prefix any string in $D$ we either report that $v = \text{locus}(P)$ even though locus($P$) = $\bot$ or report that $v$ is in $x$-range of $P$ because $m - |\text{str}(v)| \leq x$ even though $\text{str}(v)$ is not a prefix of $P$ due to fingerprint collisions. This may lead to a false positive. However, false positives are allowed in the weak prefix search problem.

Given that we can compute the fingerprint of substrings of $P$ in constant time the algorithm uses $O(m/x)$ time.

**From x-range to Exit Vertex.** We now consider how to find the exit vertex of $P$ hereafter denoted $v_e$. The algorithm is similar to the one presented in Belazzougui et al. [2] except that we support starting the search from not only the root, but from any ancestor of $v_e$.

Let $v$ be any ancestor of $v_e$, let $y$ be the smallest power of two greater than $m - |\text{str}(v)|$ and let $z$ be the largest multiple of $y$ no greater than $|\text{str}(v)|$. The search progresses by iteratively halving the search interval while using $G$ to maintain a candidate for the exit vertex and to decide in which of the two halves to continue the search.

Let $v_e$ be the candidate for the exit vertex and let $l$ and $r$ be the left and right boundary for our search interval. Initially $v_e = v$, $l = z$ and $r = z + 2y$. When $r - l = 1$, the search terminates and reports $v_e$. In each iteration, we consider the mid $b = (l + r)/2$ of the interval $[l, r]$ and update the interval to either $[b, r]$ or $[l, b]$. There are three cases:
1. $b$ is out of bounds
   a. If $b > m$ set $r$ to $b$.
   b. If $b \leq |\text{str}(v_e)|$ set $l$ to $b$.
2. $P[1,b] \in D_{\text{fat}}$, let $u$ be the corresponding vertex, i.e. $G(\phi(P[1,b])) = u$.
   a. If $|\text{str}(u)| < m$, set $v_c$ to $u$ and $l$ to $b$.
   b. If $|\text{str}(u)| \geq m$, report $u = \text{locus}(P)$ and terminate.
3. $P[1,b] \notin D_{\text{fat}}$ and thus $\phi(P[1,b])$ is not in $G$, set $r$ to $b$.

Observe that we are guaranteed that all fingerprint comparisons are collision-free in case
$P$ prefixes a string in $D$. This is because the length of the prefix fingerprints we consider are
all either 2-fattest or pseudo-fat in the skip interval of locus($P$) or one of its ancestors and
we use a fingerprinting function that is collision-free for these strings.

**Correctness.** We now show that the invariant $l \leq |\text{str}(v_e)| \leq |\text{str}(v_e)| < r$ is satisfied and
that $\text{str}(v_e)$ is a prefix of $P$ before and after each iteration. After $O(\log x)$ iterations $r - l = 1$
and thus $l = |\text{str}(v_e)| = |\text{str}(v_e)|$ and therefore $v_c = v_e$. Initially $v_c$ is an ancestor of $v_e$ and
thus $\text{str}(v_e)$ is a prefix of $P$, $l = z \leq |\text{str}(v_e)|$ and $r = z + 2y > m > |\text{str}(v_e)|$ so the invariant
is true. Now assume that the invariant is true at the beginning of some iteration and consider
the possible cases:

1. $b$ is out of bounds
   a. $b > m$ then because $|\text{str}(v_e)| \leq m$, setting $r$ to $b$ preserves the invariant.
   b. $b \leq |\text{str}(v_e)|$ then setting $l$ to $b$ preserves the invariant.
2. $P[1,b] \in D_{\text{fat}}$, let $u = G(\phi(P[1,b]))$.
   a. $|\text{str}(u)| \leq m$ then $\text{str}(u)$ is a prefix of $P$ and thus $b = \text{fat}(u) \leq |\text{str}(u)| \leq |\text{str}(v_e)|$ so
      setting $l$ to $b$ and $v_c$ to $u$ preserves the invariant.
   b. $|\text{str}(u)| > m$ then $u = G(\phi(P[1,b]))$. Then $u$ is the locus of $P$.
3. $P[1,b] \notin D_{\text{fat}}$, and thus $\phi(P[1,b])$ is not in $G$. As we are not in any of the out of bounds
cases we have $|\text{str}(v_e)| < b < m$. Thus, either $b > |\text{str}(v_e)|$ and setting $r$ to $b$ preserves
   the invariant. Otherwise $b \leq |\text{str}(v_e)|$ and thus $b$ must be in the skip interval of some
   vertex $u$ on the path from $v_e$ to $v_e$ excluding $v_c$. But skip($u$) is entirely included in $(l,r)$
   and because $b$ is 2-fattest in $(l,r)$ it is also 2-fat in skip($u$). It follows that $\text{fat}(u) = b$
   which contradicts $P[1,b] \notin D_{\text{fat}}$ and thus the invariant is preserved.

Thus if $P$ prefixes a string in $D$ we find either the exit vertex $v_e$ or the locus of $P$. In the
former case the locus of $P$ is the child of $v_e$ identified by the character $P[|\text{str}(v')| + 1]$. Having
found the vertex $u = \text{locus}(P)$ we report $[l_u, r_u]$ as the range of strings in $D$ prefixed by $P$.
In case $P$ does not prefix any strings in $D$, the fact that the fingerprint of a prefix of $P$ match
the fingerprint of some fat prefix in $D^x$ does not guarantee equality of the strings. There are
two possible consequences of this. Either the search successfully finds what it believes to be
the locus of $P$ even though locus($P$) = $\bot$ in which case we report a false positive. Otherwise,
there is no child identified by $P[|\text{str}(v')| + 1]$ in which case we can correctly report that no
strings in $D$ are prefixed by $S$, a true negative. Recall that false positives are allowed as we
are considering the weak prefix search problem.

---

1. If $b - a = 2^i$, $i > 0$ and $a$ is a multiple of $2^{i-1}$ then the mid of the interval $(a+b)/2$ is 2-fattest in $(a,b)$. 
Complexity. The size of the interval \([l, r]\) is halved in each iteration, thus we do at most \(O(\lg(m - |\text{str}(v)|))\) iterations, where \(v\) is the vertex from which we start the search. If we use the technique from the previous section to find a starting vertex in \(x\)-range of \(P\), we do \(O(\lg x)\) iterations. Each iteration takes constant time. Note that if \(P\) does not prefix a string in \(D\) we may have fingerprint collisions and we may be given a starting vertex \(v\) such that \(\text{str}(v)\) does not prefix \(P\). This can lead to a false positive, but we still have \(m - |\text{str}(v)| \leq x\) and therefore the time complexity remains \(O(\lg x)\).

Multiple Substrings. In order to answer weak prefix search queries for \(h\) substrings of a pattern \(P\) of length \(m\), we first preprocess \(P\) in \(O(m)\) time such that we can compute the fingerprint of any substring of \(P\) in constant time. We can then answer a weak prefix search query for any substring of \(P\) in total time \(O(m/x + \lg x)\) using the techniques described in the previous sections. The total time is therefore \(O(m + h(m/x + \lg x))\).

4 Distinguishing Occurrences

The following sections describe our compressed-index consisting of three independent data structures. One that finds long primary occurrences, one that finds short primary occurrences and one that finds secondary occurrences.

Let \(Z\) be the LZ77 parse of length \(x\) representing the string \(S\) of length \(n\). If \(S[i, j]\) is a phrase of \(Z\) then any substring of \(S[i, j - 1]\) is a secondary substring of \(S\). These are the substrings of \(S\) that do not contain any phrase borders. On the other hand, a substring \(S[i, j]\) is a primary substring of \(S\) when there is some phrase \(S[i', j']\) where \(i' \leq i \leq j' \leq j\), these are the substrings that contain one or more phrase borders. Any substring of \(S\) is either primary or secondary. A primary substring that match a query pattern \(P\) is a primary occurrence of \(P\) while a secondary substring that match \(P\) is a secondary occurrence [25].

5 Long Primary Occurrences

For simplicity, we assume that the data structure given in Lemma 3 not only solves the weak prefix problem, but also answers correctly when the query pattern does not prefix any of the indexed strings. Later in Section 5.3 we will see how to lift this assumption. The following data structure and search algorithm is a variation of the classical bidirectional search technique for finding primary occurrences [25].

5.1 Data Structure

For every phrase \(S[i, j]\) the strings \(S[i, j + k], 0 \leq k < \tau\) are relevant substrings unless there is some longer relevant substring ending at position \(j + k\). If \(S[i', j']\) is a relevant substring then the string \(S[j' + 1, n]\) is the associated suffix. There are at most \(\tau\) relevant substrings of \(S\) and equally many associated suffixes. The primary index is comprised by the following:

- A prefix search data structure \(T_D\) on the set of reversed relevant substrings.
- A prefix search data structure \(T_{D'}\) on the set of associated suffixes.
- An orthogonal range reporting data structure \(R\) on the \(\tau \times \tau\) grid. Consider a relevant substring \(S[i, j]\). Let \(x\) denote the rank of \(\text{rev}(S[i, j])\) in the lexicographical order of the reversed relevant substrings, let \(y\) denote the rank of its associated suffix \(S[j + 1, n]\) in the lexicographical order of the associated suffixes. Then \((x, y)\) is a point in \(R\) and along with it we store the pair \((j, b)\), where \(b\) is the position of the rightmost phrase border contained in \(S[i, j]\).
Note that every point \((x, y)\) in \(R\) is induced by some relevant substring \(S[i, j]\) and its associated suffix \(S[j + 1, n]\). If some prefix \(P[1, k]\) is a suffix of \(S[i, j]\) and the suffix \(P[k + 1, m]\) is a prefix of \(S[j + 1, n]\) then \(S[j - k + 1, j - k + m]\) is an occurrence of \(P\) and we can compute its exact location from \(k\) and \(j\).

### 5.2 Searching

The data structure can be used to find the primary occurrences of a pattern \(P\) of length \(m\) when \(m > \tau\). Consider the \(O(m/\tau)\) prefix-suffix pairs \((P[1, i\tau], P[i\tau + 1, m])\) for \(i = 1, \ldots, [m/\tau]\) and the pair \((P[1, m], \epsilon)\) in case \(m\) is not a multiple of \(\tau\). For each such pair, we do a prefix search for \(\text{rev}(P[1, i\tau])\) and \(P[i\tau + 1, m]\) in \(T_D\) and \(T_{DP}\), respectively. If either of these two searches report no matches, we move on to the next pair. Otherwise, let \([l, r], [l', r']\) be the ranges reported from the search in \(T_D\) and \(T_{DP}\) respectively. Now we do a range reporting query on \(R\) for the rectangle \([l, r] \times [l', r']\). For each point reported, let \((j, b)\) be the pair stored with the point. We report \(j - i\tau + 1\) as the starting position of a primary occurrence of \(P\) in \(S\).

Finally, in case \(m\) is not a multiple of \(\tau\), we need to also check the pair \((P[1, m], \epsilon)\). We search for \(\text{rev}(P[1, m])\) in \(T_D\) and \(\epsilon\) in \(T_{DP}\). If the search for \(\text{rev}(P[1, m])\) reports no match we stop. Otherwise, we do a range reporting query as before. For each point reported, let \((j, b)\) be the pair stored with the point. To check that the occurrence has not been reported before we do as follows. Let \(k\) be the smallest positive integer such that \(j - m + k\tau > b\). If \(k\tau > m\) we report \(j - m + 1\) as the starting position of a primary occurrence.

**Correctness.** We claim that the reported occurrences are exactly the primary occurrences of \(P\). We first prove that all primary occurrences are reported correctly. Let \(P = S[i', j']\) be a primary occurrence. As it is a primary occurrence, there must be some phrase \(S[i^*, j^*]\) such that \(i^* \leq i' \leq j^* \leq j'\). Let \(k\) be the smallest positive integer such that \(i' + k\tau - 1 \geq j^*\). There are two cases: \(k\tau \leq m\) and \(k\tau > m\). If \(k\tau \leq m\) then \(P[1, k\tau]\) is a suffix of the relevant substring ending at \(i' + k\tau - 1\). Such a relevant substring exists since \(i' + k\tau - 1 \leq j^* + \tau\).

Thus its reverse \(\text{rev}(P[1, k\tau])\) prefixes a string \(s\) in \(D\), while \(P[k\tau + 1, m]\) is a prefix of the associated suffix \(S[i' + k\tau, n]\) in \(D\). Therefore, the respective ranks of \(s\) and \(S[i' + k\tau, n]\) in \(D\) and \(D'\) are plotted as a point in \(R\) which stores the pair \((i' + k\tau - 1, b)\). We will find this point when considering the prefix-suffix pair \((P[1, k\tau], P[k\tau + 1, n])\), and correctly report \((i' + k\tau - 1) - k\tau + 1 = i'\) as the starting position of a primary occurrence. If \(k\tau > m\) then \(P[1, m]\) is a suffix of the relevant substring ending in \(i' + m - 1\). Such a relevant substring exists since \(i' + m - 1 < i' + k\tau - 1 < j^* + \tau\). Thus its reverse prefixes a string in \(D\) and trivially \(\epsilon\) is a prefix of the associated suffix. It follows as before that the ranks are plotted as a point in \(R\) storing the pair \((i' + m - 1, b)\) and that we find this point when considering the pair \((P[1, m], \epsilon)\). When considering \((P[1, m], \epsilon)\) we report \((i' + m - 1) - m + 1 = i'\) as the starting position of a primary occurrence if \(k\tau > m\), and thus \(i'\) is correctly reported.

We now prove that all reported occurrences are in fact primary occurrences. Assume that we report \(j - i\tau + 1\) for some \(i\) and \(j\) as the starting position of a primary occurrence in the first part of the procedure. Then there exist strings \(\text{rev}(S[i', j])\) and \(S[j + 1, n]\) in \(D\) and \(D'\) respectively such that \(S[i', j]\) is suffixed by \(P[1, i\tau]\) and \(S[j + 1, n]\) is prefixed by \(P[i\tau + 1, m]\). Therefore \(j - i\tau + 1\) is the starting position of an occurrence of \(P\). The string \(S[i', j]\) is a relevant suffix and therefore there exists a border \(b\) in the interval \([j - \tau + 1, j]\). Since \(i \geq 1\) the occurrence contains the border \(b\) and it is therefore a primary occurrence. If we report \(j - m + 1\) for some \(j\) as the starting position of a primary occurrence in the second part of the procedure, then \(\text{rev}(P[1, m])\) is a prefix of a string \(\text{rev}(S[i', j])\) in \(D\). It
follows immediately that $j - m + 1$ is the starting point of an occurrence. Since $m > \tau$ we have $j - m + 1 < j - \tau + 1$, and by the definition of relevant substring there is a border in the interval $[j - \tau + 1, j]$. Therefore the occurrence contains the border and is primary.

**Complexity.** We now consider the time complexity of the algorithm described. First we will argue that any primary occurrence is reported at most once and that the search finds at most two points in $R$ identifying it. Let $S[i', j']$ be a primary occurrence reported when we considered the prefix-suffix pair $(P[1, k\tau], P[k\tau + 1, m])$ as in the proof of correctness. None of the pairs $(P[1, i\tau], P[i\tau + 1, m])$, where $i < k$ will identify this occurrence as $i' + i\tau - 1 < j$.

None of the pairs $(P[1, h\tau], P[h\tau + 1, m])$, where $h > k$, will identify this occurrence. This is the case since $i' + h\tau - 1 > j + \tau - 1$, and from the definition of relevant substrings it follows that if $S[i, j]$ is a phrase, $S[a, b]$ is a relevant substring and $a < i$, then $b < i + \tau - 1$. Thus there are no relevant substrings that end after $j + \tau - 1$ and start before $i' < j$. Therefore, only one of the pairs $(P[1, i\tau], P[i\tau + 1, m])$ for $i = 1, \ldots, [m/x]$ identifies the occurrence. If $(k + 1)\tau > m$ then we might also find the occurrence when considering the pair $(P[1, m], \epsilon)$, but we do not report $i'$ as $k\tau \leq m$.

After preprocessing $P$ in $O(m)$ time, we can do the $O(m/\tau)$ prefix searches in total time $O(m + m/\tau(x/\lg x))$ where $x$ is a positive integer by Lemma 3. Using the range reporting data structure by Chan et al. [6] each range reporting query takes $(1 + k) \cdot O(B \lg \lg(z\tau))$ time where $2 \leq B \leq \lg^*(z\tau)$ and $k$ is the number of points reported. As each such point in one range reporting query corresponds to the identification of a unique primary occurrence of $P$, which happens at most twice for every occurrence we charge $O(kB \lg \lg(z\tau))$ to reporting the occurrences. The total time to find all primary occurrences is thus $O(m + \frac{m}{\tau}(\frac{m}{x} + \lg x + B \lg \lg(z\tau)) + \text{occ} B \lg \lg(z\tau))$ where $\text{occ}$ is the number of primary and secondary occurrences of $P$.

5.3 Prefix Search Verification

The prefix data structure from Lemma 3 gives no guarantees of correct answers when the query pattern does not prefix any of the indexed strings. If the prefix search gives false-positives, we may end up reporting occurrences of $P$ that are not actually there. We show how to solve this problem after introducing a series of tools that we will need.

**Straight line programs.** A straight line program (SLP) for a string $S$ is a context-free grammar generating the single string $S$.

**Lemma 4** (Rytter [36], Charikar et al. [7]). Given an LZ77 parse $Z$ of length $z$ producing a string $S$ of length $n$ we can construct a SLP for $S$ of size $O(z \lg(n/z))$ in time $O(z \lg(n/z))$.

The construction from Rytter [36] produces a balanced grammar for every consecutive substring of length $n/z$ of $S$ after a preprocessing step transforms $Z$ such that no compression element is longer than $n/z$. The height of this balanced grammar is $O(\lg n)$ and this immediately yields extracting of any substring $S[i, j]$ in time $O(\lg(n) + j - i)$. We give a simple solution to reduce this to $O(\lg(n/z) + j - i)$, that also supports computation of the fingerprint of a substring in $O(\lg(n/z))$ time.

**Lemma 5.** Given an LZ77 parse $Z$ of length $z$ producing a string $S$ of length $n$ we can build a data structure that for any substring $S[i, j]$ can extract $S[i, j]$ in $O(\lg(n/z) + j - i)$ time and compute the fingerprint $f(S[i, j])$ in $O(\lg(n/z))$ time. The data structure uses $O(z \lg(n/z))$ space and $O(n)$ construction time.
Proof. Assume for simplicity that \( n \) is a multiple of \( z \). We construct the SLP producing \( S \) from \( Z \). Along with every non-terminal of the SLP we store the size and fingerprint of its expansion. Let \( s_1, s_2, \ldots, s_k \) be consecutive length \( n/z \) substrings of \( S \). We store the balanced grammar producing \( s_i \) along with the fingerprint \( \phi(S[1, (i-1)n/z]) \) at index \( i \) in a table \( A \).

Now we can extract \( s_i \) in \( O(n/z) \) time and any substring \( s_j[j, k] \) in time \( O(\log(n/z) + k - j) \). Also, we can compute the fingerprint \( \phi(s_i[j, k]) \) in \( O(\log(n/z)) \) time. We can easily do a constant time mapping from a position in \( S \) to the grammar in \( A \) producing the substring covering that position and the corresponding position inside the substring. But then any fingerprint \( \phi(S[1, j]) \) can be computed in time \( O(\log(n/z)) \). Now consider a substring \( S[i, j] \) that starts in \( s_k \) and ends in \( s_i, k < l \). We extract \( S[i, j] \) in \( O(\log(n/z) + j - i) \) time by extracting the appropriate suffix of \( s_k \), all of \( s_m \) for \( k < m < l \) and the appropriate prefix of \( s_i \). Each of the fingerprints stored by the data structure can be computed in \( O(1) \) time after preprocessing \( S \) in \( O(n) \) time. Thus table \( A \) is filled in \( O(z) \) time and by Lemma 4 the SLPs stored in \( A \) uses a total of \( O(z \log(n/z)) \) space and construction time.

Verification of fingerprints. We need the following lemma for the verification.

Lemma 6 (Bille et al. [5]). Given a string \( S \) of length \( n \), we can find a fingerprinting function \( \phi \) that is collision-free for all length \( l \) substrings of \( S \) where \( l \) is a power of two in \( O(n \log n) \) expected time.

5.3.1 Verification Technique

Our verification technique is identical to the one given by Gagie et al. [18] and involves a simple modification of the search for long primary occurrences. By using Lemma 5 instead of bookmarking [18] for extraction and fingerprinting and because we only need to verify \( O(m/\tau) \) strings, the verification procedure takes \( O(m + m/\tau \log(n/z)) \) time and uses \( O(z \log(n/z)) \) space. See Appendix A.1 for details.

6 Short Primary Occurrences

We now describe a simple data structure that can find primary occurrences of \( P \) in time \( O(m + \text{occ}) \) using space \( O(\tau z) \) whenever \( m \leq \tau \) where \( \tau \) is a positive integer.

Let \( Z \) be the LZ77 parse of the string \( S \) of length \( n \). Let \( Z[i] = S[s_i, e_i] \) and define \( F \) to be the union of the strings \( S[k, \min\{e_i + \tau, n\}] \) where \( \max\{1, s_i, e_i - \tau\} \leq k \leq e_i \) for \( i = 1, 2, \ldots, z \). There are at most \( z\tau \) such strings, each of length \( O(\tau) \) and they are all suffixes of the \( z \) length \( 2\tau \) substrings of \( S \) starting \( \tau \) positions before each border position. We store these substrings along with the compact trie \( T_F \) over the strings in \( F \). The edge labels of \( T_F \) are compactly represented by storing references into one of the substrings. Every leaf stores the starting position in \( S \) of the string it represents and the position of the leftmost border it contains.

The combined size of \( T_F \) and the substrings we store is \( O(z\tau) \) and we simply search for \( P \) by navigating vertices using perfect hashing [16] and matching edge labels character by character. Now either \( \text{locus}(P) = \perp \) in which case there are no primary occurrences of \( P \) in \( S \); otherwise, \( \text{locus}(P) = v \) for some vertex \( v \in T_F \) and thus every leaf in the subtree of \( v \) represents a substring of \( S \) that is prefixed by \( P \). By using the indices stored with the leaves, we can determine the starting position for each occurrence and if it is primary or secondary. Because each of the strings in \( F \) start at different positions in \( S \), we will only find an occurrence once. Also, it is easy to see that we will find all primary occurrences because
of how the strings in \( F \) are chosen. It follows that the time complexity is \( O(m + \text{occ}) \) where occ is the number of primary and secondary occurrences.

## 7 The Secondary Index

Let \( Z \) be the LZ77 parse of length \( z \) representing the string \( S \) of length \( n \). We find the secondary occurrences by applying the most recent range reporting data structure by Chan et al. [6] to the technique described by Kärkkäinen and Ukkonen [25]. This gives us a secondary index using \( O(z \log \log z) \) space and \( O(\text{occ} \log \log n) \) time for reporting all secondary occurrences. For details see Appendix A.2.

## 8 The Compressed Index

We obtain our final index by combining the primary index, the verification data structure and the secondary index. We use the transformed LZ77 parse generated by Lemma 4 when building our primary index. Therefore no phrase will be longer than \( n/z \) and therefore any primary occurrence of \( P \) will have a prefix \( P[1,k] \) where \( k \leq n/z \) that is a suffix of some phrase. It then follows that we need only consider the multiples \( (P[1,\tau i], P[\tau i + 1, m]) \) for \( i < \lfloor \frac{n}{z} \rfloor \) when searching for long primary occurrences. This yields the following complexities:

- \( O(m + \min\{m,n/z\} + \frac{m}{\tau} + \log x + B \log \log (z \tau)) + \text{occ}(B \log \log (z \tau)) \) time and \( O(z \tau \log_B \log (z \tau)) \) space for the index finding long primary occurrences where \( x \) and \( \tau \) are positive integers and \( 2 \leq B \leq \log^* (z \tau) \).
- \( O(m + \text{occ}) \) time and \( O(z \log (n/z)) \) space for the index finding short primary occurrences.
- \( O(m + m/\tau \log (n/z)) \) time and \( O(z \log (n/z)) \) space for the verification data structure.
- \( O(\text{occ} \log \log n) \) time and \( O(z \log \log z) \) space for the secondary index.

If we fix \( x \) at \( n/z \) we have \( \min\{m,n/z\} \frac{m}{\tau} \leq m \) in which case we obtain the following trade-off simply by combining the above complexities.

**Theorem 7.** Given a string \( S \) of length \( n \) from an alphabet of size \( \sigma \) compressed using LZ77 to a string of length \( z \) we can build a compressed-index supporting substring queries in \( O(m + \min\{m,n/z\} + \frac{m}{\tau} + \log x + B \log \log (z \tau)) + \text{occ}(B \log \log (z \tau)) + \log \log n) \) time using \( O(z \log (n/z) + \tau \log_B \log (z \tau) + \log \log z)) \) space for any query pattern \( P \) of length \( m \) where \( 2 \leq B \leq \log^* (z \tau), \) \( 0 < \epsilon < 1 \) and \( \tau \) is a positive integer.

We note that none of our data structures assume constant sized alphabet and thus Theorem 7 holds for any alphabet size.

Due to lack of space the description and analysis of the preprocessing have been moved to Appendix 8.2.

### 8.1 Trade-offs

Theorem 7 gives rise to a series of interesting time-space trade-offs.

**Corollary 8.** Given a string \( S \) of length \( n \) from an alphabet of size \( \sigma \) compressed using LZ77 into a string of length \( z \) we can build a compressed-index supporting substring queries in

1. \( O(m(1 + \frac{\log x}{\log (n/z)}) + \text{occ} \log \log n) \) time using \( O(z \log (n/z) \log \log z) \) space, or
2. \( O(m(1 + \frac{\log \log n}{\log (n/z)}) + \text{occ}(\log \log n + \log^* z)) \) time using \( O(z \log (n/z)) \) space, or
3. \( O(m \log^* (n/z) + \text{occ} \log \log n) \) time using \( O(z \log (n/z)) \) space, or
4. \( O(m + \text{occ} \log \log n) \) time using \( O(z(\log (n/z) \log \log z + \log \log^2 z)) \) space, or

CPM 2017
(v) $O(m + \text{occ}(\lg \lg n + \lg^e z))$ time using $O(z(\lg(n/z) + \lg^e z))$ space.
for any $0 < \epsilon < 1$ and $0 < \epsilon' < 1$.

**Proof.** For (i) set $B = 2$ and $\tau = \lg(n/z)$, for (ii) set $B = \lg^e z$ and $\tau = \lg(n/z)$, for (iii) set $B = 2$ and $\tau = \lg^e n/z$ for some $0 < \epsilon' < 1$, for (iv) set $B = 2$ and $\tau = \lg(n/z) + \lg\lg z$, for (v) set $B = \lg^e (z)$ and $\tau = \lg(n/z) + \lg^e z$. □

The leading term in the time complexity of Corollary 8 (i) is $O(m)$ whenever $\lg\lg(z) = O(\lg(n/z))$ which is true when $z = O(n/\lg n)$, i.e. for all strings that are compressible by at least a logarithmic fraction. For $\sigma = O(1)$ we have $z = O(n/\lg n)$ all strings [34] and thus Theorem 1 (i) follows immediately. Corollary 8 (ii) matches previous best space bounds but obtains a leading term of $O(m)$ for any polynomial compression rate. Theorem 1 (ii) is a weaker version of this because it assumes constant sized alphabet and therefore follows immediately. Corollary 8 (iii) matches the space and time for reporting occurrences of previous best bounds by Gagie et al. [18] but with a leading term of $O(m \lg^e (n/z))$ compared to a leading term of $O(m \lg m)$. Corollary 8 (iv) and (v) show how to guarantee the fast query times with leading term $O(m)$ without the assumptions on compression ratio that (i) and (ii) require to match this, but at the cost of increased space.

### 8.2 Preprocessing

We now consider the preprocessing time of the data structure. Let $Z$ be the LZ77 parse of the string $S$ of length $n$ let $T_D$ and $T_D'$ be the compact tries used in the index for long primary occurrences. The compact trie $T_D$ index $O(\tau z)$ substrings of $S$ with overall length $O(n\tau)$. Thus we can construct the trie in $O(n\tau)$ time by sorting the strings and successively inserting them in their sorted order [1]. The compact tries $T_D'$ index $z\tau < n$ suffixes of $S$ and can be built in $O(n)$ time using $O(n)$ space [10]. The index for short primary occurrences is a generalized suffix tree over $z$ strings of length $O(\tau)$ with total length $z\tau < n$ and is therefore also built in $O(n)$ time. The dictionaries used by the prefix search data structures and for trie navigation contain $O(\tau z)$ keys and are built in expected linear time using perfect hashing [16]. The range reporting data structures used by the primary and secondary index over $O(\tau z)$ points are built in $O(\tau z \lg \gamma(\tau z))$ expected time using Lemma 9.

Building the SLP for our verification data structure takes $O(z \lg(n/z))$ time using Lemma 4 and finding an appropriate fingerprinting function $\phi$ takes $O(n \lg n)$ expected time using Lemma 6. The prefix search data structures $T_D$ and $T_D'$ also require that $\phi$ is collision-free for the $x$-prefixes, fat prefixes and the prefixes with pseudo fat lengths. There are at most $O(\tau z \lg n)$ such prefixes [2]. If we compute these fingerprints incrementally while doing a traversal of the tries, we expect all the fingerprints to be unique. We simply check this by sorting the fingerprints in linear time and checking for duplicates by doing a linear scan. If we choose a prime $p = \Theta(n^5)$ for the fingerprinting function then the probability of a collision between any two strings is $O(1/n^4)$ [35] and by a union bound over the $O((n \lg n)^2)$ possible collisions the probability that $\phi$ is collision-free is at least $1 - 1/n$. Thus the expected time to find our required fingerprinting function is $O(n + n \lg n)$.

All in all, the preprocessing time for our combined index is therefore expected $O(n \lg n + n\tau)$.

16:14 Time-Space Trade-Offs for Lempel-Ziv Compressed Indexing

Consider the string $S$ of length $n$ that we wish to index and let $Z$ be the LZ77 parse of $S$. The verification data structure is given by Lemma 5. Consider the prefix search data structure $T_D$ as given in Section 5.1 and let $\phi$ be the fingerprinting function used by the prefix search, the case for $T_D$ is symmetric. We alter the search for primary occurrences such that it first does the $O(m/\tau)$ prefix searches, then verifies the results and discards false-positives before moving on to do the $O(m/\tau)$ range reporting queries on the verified results. We also modify $\phi$ using Lemma 6 to be collision-free for all substrings of the indexed strings which length is a power of two.

Let $Q_1, Q_2, \ldots, Q_j$ be the all the suffixes of $P$ for which the prefix search found a locus candidate, let the candidates be $v_1, v_2, \ldots, v_j \in T_{D'}$ and let $p_i$ be $\text{str}(v_i)[1, |Q_i|]$. Assume that $|Q_i| < |Q_{i+1}|$, and let 2-suf$(Q)$ and 2-pre$(Q)$ denote the fingerprints using $\phi$ of the suffix and prefix respectively of length $2^{|v(Q)|}$ of some string $Q$. The verification progresses in iterations. Initially, let $a = 1$, $b = 2$ and for each iteration do as follows:

1. 2-suf$(Q_a) \neq$ 2-suf$(p_a)$ or 2-pre$(Q_a) \neq$ 2-pre$(p_a)$: Discard $v_a$ and set $a = a + 1$ and $b = b + 1$.
2. 2-suf$(Q_a) = 2$-suf$(p_a)$ and 2-pre$(Q_a) = 2$-pre$(p_a)$, let $R = p_b[|p_a| - |p_b| + 1, |p_a|]$. 
   a. 2-suf$(R) = 2$-suf$(Q_a)$ and 2-pre$(R) = 2$-pre$(Q_a)$: set $a = a + 1$ and $b = b + 1$.
   b. 2-suf$(R) \neq 2$-suf$(Q_a)$ or 2-pre$(R) \neq 2$-pre$(Q_a)$: discard $v_b$ and set $b = b + 1$. 

A.1 Verification Technique

A Appendix

A.1 Verification Technique

Consider the string $S$ of length $n$ that we wish to index and let $Z$ be the LZ77 parse of $S$. The verification data structure is given by Lemma 5. Consider the prefix search data structure $T_D$ as given in Section 5.1 and let $\phi$ be the fingerprinting function used by the prefix search, the case for $T_D$ is symmetric. We alter the search for primary occurrences such that it first does the $O(m/\tau)$ prefix searches, then verifies the results and discards false-positives before moving on to do the $O(m/\tau)$ range reporting queries on the verified results. We also modify $\phi$ using Lemma 6 to be collision-free for all substrings of the indexed strings which length is a power of two.
3. \( b = j + 1 \): If all vertices have been discarded, report no matches. Otherwise, let \( v_f \) be the last vertex considered, that was not discarded. Compare \( p_f \) to \( Q_f \) and if equal, report all non-discarded vertices as verified. Otherwise discard all vertices and report no matches.

Consider the correctness and complexity of the algorithm. In case 1, clearly, \( p_a \) does not match \( Q_a \) and thus \( v_a \) must be a false-positive. Now observe that because \( Q_i \) is a suffix of \( P \), it is also a suffix of \( Q_i' \) for any \( i < i' \). Thus in case 2 (b), if \( R \) does not match \( Q_a \) then \( v_b \) must be a false-positive. In case 2 (a), both \( v_a \) and \( v_b \) may still be false-positives, yet by Lemma 6, \( p_a \) is a suffix of \( p_b \) because 2-suf \( p_a \) = 2-suf \( R \) and 2-pre \( p_a \) = 2-pre \( R \). Finally, in case 3, \( v_f \) is a true positive if and only if \( p_f = Q_f \). But any other non-discarded vertex \( v_i \neq v_f \) is also only a true positive if \( p_f = Q_f \) because \( p_i \) is a suffix of \( p_f \) and \( Q_i \) is a suffix of \( Q_p \).

The algorithm does \( j \) iterations and fingerprints of substrings of \( P \) can be computed in constant time after \( O(m) \) preprocessing. Every vertex \( v \in T_D' \) represents one or more substrings of \( S \). If we store the starting index in \( S \) of one of these substrings in \( v \) when constructing \( T_D' \) we can compute the fingerprint of any substring \( \text{str}(v)[i,j] \) by computing the fingerprint of \( S[i'+i-1,i'+j-1] \) where \( i' \) is the starting index of one of the substring of \( S \) that \( v \) represents. By Lemma 5, the fingerprint computations take \( O(\log(n/z)) \) time and because \( j \leq m/\tau \) the total time complexity of the algorithm is \( O(m + m/\tau \log(n/z)) \).

### A.2 Secondary Index

Let \( Z \) be the LZ77 parse of length \( z \) representing the string \( S \) of length \( n \). We find the secondary occurrences by applying the most recent range reporting data structure by Chan et al. [6] to the technique described by Kärkkäinen and Ukkonen [25] which is inspired by the ideas of Farach and Thorup [11].

Let \( X \subseteq \{0,\ldots,u\}^d \) be a set of points in a \( d \)-dimensional grid. The orthogonal range reporting problem in \( d \)-dimensions is to compactly represent \( X \) while supporting range reporting queries, that is, given a rectangle \( R = [a_1,b_2] \times \cdots \times [a_d,b_d] \) report all points in the set \( R \cap X \). We use the following results for 2-dimensional range reporting:

- **Lemma 9** (Chan et al. [6]). For any set of \( n \) points in \([0,u] \times [0,u] \) and \( 2 < B < \lg^* n, 0 < \epsilon < 1 \) we can solve \( 2 \)-d orthogonal range reporting with \( O(n \log n) \) expected preprocessing time, \( O(n \log n \log u) \) space and \((1 + k) \cdot O(B \log u) \) query time where \( k \) is the number of occurrences inside the rectangle.

Let \( o_1,\ldots,o_{occ} \) be the starting positions of the occurrences of \( P \) in \( S \) ordered increasingly. Assume that \( o_1 \) is a secondary occurrence such that \( P = S[o_h, o_h+m-1] \). Then by definition, \( S[o_h, o_h+m-1] \) is a substring the prefix \( S[i,j-1] \) of some phrase \( S[i,j] \) and there must be an occurrence of \( P \) in the source of that phrase. More precise, let \( S[k,l] = S[i,j-1] \) be the source of the phrase \( S[i,j] \) then \( o_{h'} = k + o_h - i \) is an occurrence of \( P \) for some \( h' < h \). We say that \( o_{h'} \) which may be primary or secondary, is the source occurrence of the secondary occurrence \( o_h \) given the LZ77 parse of \( S \). Thus every secondary occurrence has a source occurrence. Note that it follows from the definition that no primary occurrence has a source occurrence.

We find the secondary occurrences as follows: Build a range reporting data structure \( Q \) on the \( n \times n \) grid and if \( S[i,j] \) is a phrase with source \( S[i',j'] \) we plot a point \((i',j')\) and along with it we store the phrase start \( i \).

Now for each primary occurrence \( o \) found by the primary index, we query \( Q \) for the rectangle \([0,o] \times [o+m-1,n] \). The points returned are exactly the occurrences having
$o$ as source. For each point $(x, y)$ and phrase start $i$ reported, we report an occurrence $o' = i + o - x$ and recurse on $o'$ to find all the occurrences having $o'$ as source.

Because no primary occurrence have a source, while all secondary occurrences have a source, we will find exactly the secondary occurrences.

The range reporting structure $Q$ is built using Lemma 9 with $B = 2$ and uses space $O(z \lg \lg z)$. Exactly one range reporting query is done for each primary and secondary occurrence each taking $O((1 + k) \lg \lg n)$ where $k$ is the number of points reported. Each reported point identifies a secondary occurrence, so the total time is $O(occ \lg \lg n)$.  

From LZ77 to the Run-Length Encoded Burrows-Wheeler Transform, and Back

Abstract

The Lempel-Ziv factorization (LZ77) and the Run-Length encoded Burrows-Wheeler Transform (RLBWT) are two important tools in text compression and indexing, being their sizes \( z \) and \( r \) closely related to the amount of text self-repetitiveness. In this paper we consider the problem of converting the two representations into each other within a working space proportional to the input and the output. Let \( n \) be the text length. We show that RLBWT can be converted to LZ77 in \( O(n \log r) \) time and \( O(r) \) words of working space. Conversely, we provide an algorithm to convert LZ77 to RLBWT in \( O(n(\log r + \log z)) \) time and \( O(r + z) \) words of working space. Note that \( r \) and \( z \) can be constant if the text is highly repetitive, and our algorithms can operate with (up to) exponentially less space than naive solutions based on full decompression.

1 Introduction

The field of compressed computation – i.e. computation on compressed representations of the data without first fully decompressing it – is lately receiving much attention due to the ever-growing rate at which data is accumulating in archives such as the web or genomic databases. Being able to operate directly on the compressed data can make an enormous difference, considering that repetitive collections, such as sets of same-species genomes or software repositories, can be compressed at rates that often exceed 1000x. In such cases, this set of techniques makes it possible to perform most of the computation directly in primary memory and enables the possibility of manipulating huge datasets even on resource-limited machines.

Central in the field of compressed computation are compressed data structures such as compressed full-text indexes, geometry (e.g. 2D range search), trees, graphs. The compression of these structures (in particular those designed for unstructured data) is based on a set of techniques which include entropy compression, Lempel-Ziv parsings [16, 17] (LZ77/LZ78), grammar compression [6], and the Burrows-Wheeler transform [4] (BWT).
Grammar compression, Run-Length encoding of the BWT [14, 13] (RLBWT), and LZ77 have been shown superior in the task of compressing highly-repetitive data and, as a consequence, much research is lately focusing on these three techniques.

In this paper we address a central point in compressed computation: can we convert between different compressed representations of a text while using an amount of working space proportional to the input/output (i.e. sizes of the compressed files)? Being able to perform such task would, for instance, open the possibility of converting between compressed data structures (e.g. self-indexes) based on different compressors, all within compressed working space.

It is not the first time that this problem has been addressed. In [12] the author shows how to convert the LZ77 encoding of a text into a grammar-based encoding, while in [2, 1] the opposite direction (though pointing to LZ78 instead of LZ77) is considered. In [15] the authors consider the conversions between LZ78 and run-length encoding of the text. Note that LZ77 and run-length encoding of the BWT are much more powerful than LZ78 and run-length encoding of the text, respectively, so methods addressing conversion between LZ77 and RLBWT would be of much higher interest. In this work we show how to efficiently solve this problem in space proportional to the sizes of these two compressed representations. See Basics section for a formal definition of RLBWT(T) and LZ77(T) as a list of r pairs and z triples, respectively. Let RLBWT(T) → LZ77(T) denote the computation of the list LZ77(T) using as input the list RLBWT(T) (analogously for the opposite direction). The following results are illustrated below:

1. We can compute RLBWT(T) → LZ77(T) in $O(n \log r)$ time and $O(r)$ words of working space
2. We can compute LZ77(T) → RLBWT(T) in $O(n(\log r + \log z))$ time and $O(r + z)$ words of working space

Result (1) is based on our own recent work [10] and requires space proportional to the input only as output is streamed to disk. Result (2) requires space proportional to the input plus the output, since data structures based on both compressors are used in main memory. In order to achieve result (2), we show how we can (locally) decompress LZ77(T) while incrementally building a run-length BWT data structure of the reversed text. Extracting text from LZ77 is a computationally expensive task as it requires a time proportional to the parse height $h$ per extracted character [8] (with $h$ as large as $n$, in the worst case). The key ingredient of our solution is to use the run-length BWT data structure itself to efficiently extract text from LZ77(T).

2 Basics

We assume that our text $T$ is of the form $T = T'\# \in \Sigma^n$, with $T' \in (\Sigma \setminus \{\#\})^{n-1}$. Character # is lexicographically smaller than all elements in $\Sigma$ and plays the role of both BWT and LZ77 terminators.

The Burrows-Wheeler Transform [4] $BWT(T)$ is a permutation of $T$ defined as follows. Sort all cyclic permutations of $T$ in a conceptual matrix $M \in \Sigma^{n \times n}$. $BWT(T)$ is the last column of $M$. With $F$ and $L$ we will denote the first and last column of $M$, respectively, and we will say $F$-positions and $L$-positions to refer to positions on these two columns. On compressible texts, $BWT(T)$ exhibits some remarkable properties that permit to boost compression. In particular, it can be shown [13] that repetitions in $T$ generate equal-letter runs in $BWT(T)$. We can efficiently represent this transform as the list of pairs

$$RLBWT(T) = \langle \lambda_i, c_i \rangle_{i=1,...,r_T}$$
where \( \lambda_i > 0 \) is the length of the maximal \( i \)-th \( c_i \)-run, \( c_i \in \Sigma \). Equivalently, \( RLBWT(T) \) is the shortest list of pairs \( (\lambda_i, c_i) \)\( i = 1, \ldots, r_T \) satisfying \( BWT(T) = c_1^{\lambda_1} c_2^{\lambda_2} \cdots c_n^{\lambda_n} \). Let \( \overrightarrow{BWT} \) be the reverse of \( T \). To simplify notation we define \( r = \max\{r_T, r_{\overrightarrow{T}}\} \) (in practical cases \( r_T \approx r_{\overrightarrow{T}} \) holds [3], and this definition simplifies notation).

**Example 1.** Let \( T = \text{abcabcaabcaabcabc} \). Then, \( \text{BWT}(T) = \text{cccccc#aaabbaabbbb} \) and \( \text{RLBWT}(T) = (5, c)(1, #)(3, a)(2, b)(3, a)(5, b) \). The Burrows-Wheeler transform has \( r = 6 \) equal-letter runs.

With \( RLBWT^+(T) \) we denote a run-length encoded BWT data structure on the text \( T \), taking \( O(r) \) words of space and supporting \text{insert}, \text{rank}, \text{select}, \text{and access} \) operations on the string \( B = BWT(T) \). These operations are defined as follows:

- \text{insert}(c, i)\), where \( c \in \Sigma \) and \( i < n \), turns \( B \) into \( B[0, \ldots, i - 1]cB[i, \ldots, n - 1] \)
- \text{rank}(c, i)\) returns the number of characters equal to \( c \) in \( B[0, \ldots, i - 1] \)
- \text{select}(c, i)\) returns the position \( j \) such that \( B[j] = c \) and \( \text{rank}(c, j) = i \)
- \text{access}(i)\) returns \( B[i] \)

Using these operations, functions \( RLBWT.LF(i) \) and \( RLBWT.LF(j) \) (mapping \( L \)-positions to \( F \)-positions and vice versa) and function \text{extend} \((\text{mapping } RLBWT^+(T) \text{ into } RLBWT^+(aT) \text{ for some } a \in \Sigma) \) can be supported in \( O(\log r) \) time. We leave to the next sections details concerning the particular implementation of this data structure. With \( RLBWT.LF^k(i) \) we denote the application of function \( LF \) \( k \) times starting from \( L \)-position \( i \).

We recall that \( BWT(T) = \overrightarrow{BWT} \) can be built online with an algorithm that reads \( T \)-characters left-to-right and inserts them in a dynamic string data structure [7, 5]. Briefly, letting \( a \in \Sigma \), the algorithm is based on the idea of backward-searching the extended reversed text \( \overrightarrow{BWT} \) in the BWT index for \( \overrightarrow{T} \). This operation leads to the \( F \)-position \( l \) where \( \overrightarrow{BWT} \) should appear among all sorted \( \overrightarrow{T} \)'s suffixes. At this point, it is sufficient to insert \( # \) at position \( l \) in \( BWT(\overrightarrow{T}) \) and replace the old \( # \) with \( a \) to obtain \( BWT(\overrightarrow{T}) \).

The \( \text{LZ77 parsing} [16] \) (or factorization) of a text \( T \) is the sequence of phrases (or factors)

\[
\text{LZ77}(T) = (\pi_i, \lambda_i, c_i)_{i=1, \ldots, z}
\]

where \( \pi_i \in \{0, \ldots, n-1\} \cup \{\bot\} \) and \( \bot \) stands for “undefined”, \( \lambda_i \in \{0, \ldots, n-2\} \), \( c_i \in \Sigma \), and:

1. \( T = \omega_1 c_1 \ldots \omega_2 c_2 \) with \( \omega_1 = \epsilon \) if \( \lambda_1 = 0 \) and \( \omega_i = T[\pi_i, \ldots, \pi_i + \lambda_i - 1] \) otherwise.
2. For any \( i = 1, \ldots, z \), the string \( \omega_i \) is the longest occurring at least twice in \( \omega_1 c_1 \ldots \omega_i \).

**Example 2.** Let \( T = \text{abcabcaabcaabcabc} \). The \( \text{LZ77} \) factorization of the text is \( \text{abc|b|abc|ca|abc|abc|abc#} \). This factorization can be compactly represented as the list of triples \( \text{LZ77}(T) = (\bot, 0, a)(\bot, 0, b)(\bot, 0, c)(0, 2, b)(2, 2, a)(1, 4, c)(3, 4, #) \). The number of phrases is \( z = 7 \).

## 3 From RLBWT to LZ77

Our algorithm to compute \( RLBWT(T) \to LZ77(T) \) is based on the result [10]: an algorithm to compute – in \( O(r) \) words of working space and \( O(n \log r) \) time – \( \text{LZ77}(T) \) using \( T \) as input. The data structure at the core of this result is a dynamic run-length compressed string; we recall the bounds of such structure as we will use it several times in the rest of the paper.
From LZ77 to RLBWT

The algorithm described in [10] works in two steps, during the first of which builds $RLBWT^+(\overline{T})$ by inserting left-to-right $T$-characters in a dynamic $RLBWT$ represented with the data structure of Theorem 3 – using the BWT construction procedure sketched in the previous section. In the second step, the procedure scans $T$ once more left-to-right while searching (reversed) LZ77 phrases in $RLBWT^+(\overline{T})$. At the same time we store, for each BWT equal-letter run, the two most external (i.e., leftmost and rightmost in the run) text positions seen up to the current position; the key property proved in [10] is that this sampling is sufficient to locate LZ77 phrase boundaries and sources. LZ77 phrases are outputted in text order, therefore they can be directly streamed to output. The total size of the sampling of text positions never exceeds $2r$. From Theorem 3, all operations on $RLBWT^+(\overline{T})$ (insert, LF-function requires just an access and a rank on the F column and a select on the L column. From Theorem 3, all these operations are supported in $O(\log r)$ time, so also step 2 terminates in $O(n \log r)$ time. Recall that $r$ is defined to be the maximum between the number of runs in $BWT(T)$ and $BWT(\overline{T})$. Since in this step we are building $RLBWT^+(\overline{T})$ using $RLBWT^+(T)$, the overall space is bounded by $O(r)$ words. Finally, step 3 terminates in $O(n \log r)$ time while using $O(r)$ words of space [10]. The claimed bounds for our algorithm to compute $RLBWT(T) \to LZ77(T)$ follow.

**Theorem 4.** Conversion $RLBWT(T) \to LZ77(T)$ can be performed in $O(n \log r)$ time and $O(r)$ words of working space.

Proof. We use the dynamic RLBWT structure of Theorem 3 to implement components $RLBWT^+(T)$ and $RLBWT^+(\overline{T})$. Step 1 requires $n$ insert operations in $RLBWT^+(T)$, and terminates therefore in $O(n \log r)$ time. Since the string we are building contains $r$ runs, this step uses $O(r)$ words of working space. Step 2 calls $n$ extend and LF queries on dynamic RLBWTs. extend requires a constant number of rank and insert operations [5]. FL function requires just an access and a rank on the F column and a select on the L column. From Theorem 3, all these operations are supported in $O(\log r)$ time, so also step 2 terminates in $O(n \log r)$ time.

Our strategy to convert $LZ77(T)$ to $RLBWT(T)$ consists of the following steps:

1. convert $RLBWT(T)$ to $RLBWT^+(T)$, i.e. add support for rank/select/access queries on $RLBWT(T)$;
2. compute $RLBWT^+(\overline{T})$ using $RLBWT^+(T)$;
3. run the algorithm described in [10] and compute $LZ77(T)$ using $RLBWT^+(\overline{T})$.

Let $RLBWT(T) = (\lambda_1, c_1), \ldots, (\lambda_r, c_r)$ (see the previous section). Step 1 can be performed by just inserting characters $c_1^\lambda, c_2^\lambda, \ldots, c_r^\lambda$ (in this order) in a dynamic run-length encoded string. Step 2 is performed by extracting characters $T[0], T[1], \ldots, T[n-1]$ from $RLBWT^+(T)$ and inserting them (in this order) in a dynamic $RLBWT$ data structure with the BWT construction algorithm sketched in the Section (2). Since this algorithm builds the RLBWT of the reversed text, the final result is $RLBWT^+(\overline{T})$. We can state our first result:

**Theorem 3 ([9, 10]).** Let $T \in \Sigma^n$ and let $\bar{r}$ be the number of equal-letter runs in $T$. There exists a data structure taking $O(\bar{r})$ words of space and supporting rank, select, access, and insert operations on $T$ in $O(\log \bar{r})$ time.
1. extract $T[0], T[1], \ldots, T[n-1]$ from $LZ77(T)$ and add them (one by one) in $RLBWT^+(\hat{T})$ (note: decompression is local. We discard $T[i]$ after inserting it in $RLBWT^+(\hat{T})$);

2. convert $RLBWT^+(\hat{T})$ to $RLBWT^+(T)$;

3. extract equal-letter runs from $RLBWT^+(T)$ and stream $RLBWT(T)$ to the output.

Step 2 is analogous to step 2 discussed in the previous section. Step 3 requires reading characters $RLBWT^+(T)[0], \ldots, RLBWT^+(T)[n-1]$ (access queries on $RLBWT^+(T)$) and keeping in memory a character storing last run’s head and a counter keeping track of last run’s length. Whenever we open a new run, we stream last run’s head and length to the output.

The problematic step is the first. As mentioned in the introduction, extracting a character from $LZ77(T)$ requires to follow a chain of character copies. In the worst case, the length $h$ of this chain – also called the parse height (see [8] for a formal definition) – can be as large as $n$ (even though in the average case $h$ is small, see [8] for an experimental evaluation).

Our observation is that, since we are building $RLBWT^+(\hat{T})$, we can use this component to extract text from $LZ77(T)$ without following the chain of $LZ77$-character copies: while decoding factor $(\pi_v, \lambda_v, c_v)$, we convert text position $\pi_v$ to its corresponding RLBWT position $j = RLBWT.LF^{\pi_v}(0)$ and extract $\lambda_v$ characters by performing $\lambda_v$ further LF queries from position $j$. Conceptually, this task could be achieved by directly performing $\pi_v$ LF queries on the RLBWT starting from $L$-position 0. This is clearly not efficient as it would result in a quadratic-time strategy. In the next section we show how to compute $RLBWT.LF^{\pi_v}(0)$ in just $O(\log z)$ time.

### 4.1 Dynamic functions

Considering that $RLBWT^+(T)$ is built incrementally, we need a data structure to encode a function $\mathcal{Z} : \{\pi_1, \ldots, \pi_z\} \rightarrow \{0, \ldots, n - 1\}$ mapping those text positions that are the source of some $LZ77$ phrase to their corresponding $RLBWT$ positions. Moreover, the data structure must be dynamic, that is it must support the following three operations (see below the list for a description of how these operations will be used):

- **map:** $\mathcal{Z}(i)$. Compute the image of $i$
- **expand:** $\mathcal{Z}.expand(j)$. Set $\mathcal{Z}(i)$ to $\mathcal{Z}(i) + 1$ for every $i$ such that $\mathcal{Z}(i) \geq j$
- **assign:** $\mathcal{Z}(i) \leftarrow j$. Call $\mathcal{Z}.expand(j)$ and set $\mathcal{Z}(i)$ to $j$

To keep the notation simple and light, we use the same symbol $\mathcal{Z}$ for the function as well as for the data structure representing it. We say that $\mathcal{Z}(i)$ is defined if, for some $j$, we executed an **assign** operation $\mathcal{Z}(i) \leftarrow j$ at some previous stage of the computation. For technical reasons that will be clear later, we restrict our attention to the case where we execute **assign** operations $\mathcal{Z}(i) \leftarrow j$ for increasing values of $i$, i.e. if $\mathcal{Z}(i_1) \leftarrow j_1, \ldots, \mathcal{Z}(i_q) \leftarrow j_q$ is the sequence (in temporal order) of the calls to **assign** on $\mathcal{Z}$, then $i_1 < \cdots < i_q$. This will be the case in our algorithm and, in particular, $i_1, \ldots, i_q$ will be the sorted non-null phrases sources $\pi_1, \ldots, \pi_z$. Finally, we assume that $\mathcal{Z}(i)$ is always called when $\mathcal{Z}(i)$ has already been defined – again, this will be the case in our algorithm.

Intuitively, $\mathcal{Z}.expand(j)$ will be used when we insert $T[i]$ at position $j$ in the partial $RLBWT^+(\hat{T})$ and $j$ is not associated with any phrase source (i.e. $i \neq \pi_v$ for all $v = 1, \ldots, z$). When we insert $T[i]$ at position $j$ in the partial $RLBWT^+(\hat{T})$ and $i = \pi_v$ for some $v = 1, \ldots, z$ (possibly more than one), $\mathcal{Z}(i) \leftarrow j$ will be used.

The existence and associated query-costs of the data structure $\mathcal{Z}$ are proved in the following lemma.
Lemma 5. Letting \( z \) be the number of phrases in the LZ77 parsing of \( T \), there exists a data structure taking \( O(z) \) words of space and supporting \textit{map}, \textit{expand}, and \textit{assign} operations on \( Z : \{\pi_1, \ldots, \pi_z\} \to \{0, \ldots, n - 1\} \) in \( O(\log z) \) time.

Proof. First of all notice that, since \( LZ77(T) \) is our input, we know beforehand the domain \( D = \{\pi | \langle \pi, \lambda, c \rangle \in LZ77(T) \land \pi \neq \bot\} \) of \( Z \). We can therefore map the domain to rank space and restrict our attention to functions \( Z' : \{0, \ldots, d - 1\} \to \{0, \ldots, n - 1\} \), with \( d = |D| \leq z \). To compute \( Z(i) \) we map text position \( 0 \leq i < n \) to a rank \( 0 \leq i' < d \) by binary-searching a precomputed array containing the sorted values of \( D \) and return \( Z'(i') \). Similarly, \( Z(i) \leftarrow j \) is implemented by executing \( Z'(i') \leftarrow j \) (with \( i' \) defined as above), and \( Z.expand(j) \) simply as \( Z'.expand(j) \).

We use a dynamic gap-encoded bitvector \( C \) marking (by setting a bit) those positions \( j \) such that \( j = Z(i) \) for some \( i \). A dynamic gap-encoded bitvector with \( b \) bits set can easily be implemented using a red-black tree such that it takes \( O(b) \) words of space and supports \textit{insert}, \textit{rank}, \textit{select}, and \textit{access} operations in \( O(\log b) \) time; see [10] for such a reduction. Upon initialization of \( Z \), \( C \) is empty. Let \( k \) be the number of bits set in \( C \) at some step of the computation. We can furthermore restrict our attention to \textit{surjective} functions \( Z'' : \{0, \ldots, d - 1\} \to \{0, \ldots, k - 1\} \) as follows. \( Z'(i') \) (\textit{map}) returns \( C.select_1(Z''(i')) \). The \textit{assign} operation \( Z'(i') \leftarrow j \) requires the \textit{insert} operation \( C.insert(1, j) \) followed by the execution of \( Z''(i') \leftarrow C.rank_1(j) \). Operation \( Z'.expand(j) \) is implemented with \( C.insert(0, j) \).

To conclude, since we restrict our attention to the case where \( \text{when calling} \ (Z(i) \leftarrow j) \) \( (i') \) is defined, we will execute \textit{assign} operations \( Z''(i') \leftarrow j'' \) for increasing values of \( i' = 0, 1, \ldots, d - 1 \). In particular, at each \textit{assign} \( Z''(i') \leftarrow j'' \), \( i' = k \) will be the current domain size. We therefore focus on a new operation, \textit{append}, denoted as \( Z''.append(j'') \) and whose effect is \( Z''(k) \leftarrow j'' \). We are left with the problem of finding a data structure for a \textit{dynamic permutation} \( Z'' : \{0, \ldots, k - 1\} \to \{0, \ldots, k - 1\} \) with support for \textit{map} and \textit{append} operations. Note that both domain and codomain size \( (k) \) are incremented by one after every \textit{append} operation.

Example 6. Let \( k = 5 \) and \( Z'' \) be the permutation \( (3,1,0,4,2) \). After \( Z''.append(2) \), \( k \) increases to 6 and \( Z'' \) turns into the permutation \( (4,1,0,5,3,2) \). Note that \( Z''.append(j'') \) has the following effect on the permutation: all numbers larger than or equal to \( j'' \) are incremented by one, and \( j'' \) is appended at the end of the permutation.

To implement the dynamic permutation \( Z'' \), we use a red-black tree \( T \). We associate to each internal tree node \( x \) a counter storing the number of leaves contained in the subtree rooted in \( x \). Let \( m \) be the size of the tree. The tree supports two operations:

1. \( T.insert(j) \). Insert a new leaf at position \( j \), i.e. the new leaf will be the \( j \)-th leaf to be visited in the in-order traversal of the tree. This operation can be implemented using subtree-size counters to guide the insertion. After the leaf has been inserted, we need to re-balance the tree (if necessary) and update at most \( O(\log m) \) subtree-size counters. The procedure returns (a pointer to) the tree leaf \( x \) just inserted. Overall, \( T.insert(j) \) takes \( O(\log m) \) time
2. \( T.locate(x) \). Take as input a leaf in the red-black tree and return the (0-based) rank of the leaf among all leaves in the in-order traversal of the tree. \( T.locate(x) \) requires climbing the tree from \( x \) to the root and use subtree-size counters to retrieve the desired value, and therefore runs in \( O(\log m) \) time.

At this point, the dynamic permutation \( Z'' \) is implemented using the tree described above and a vector \( N \) of red-black tree leaves supporting \textit{append} operations (i.e. insert at the end
of the vector). $N$ can be implemented with a simple vector of words with initial capacity 1. Every time we need to add an element beyond the capacity of $N$, we re-allocate $2|N|$ words for the array. $N$ supports therefore constant-time access and amortized constant-time append operations. Starting with empty $T$ and $N$, we implement operations on $Z''$ as follows:

- $Z''.\text{map}(i)$ returns $T.\text{locate}(N[i])$
- $Z''.\text{append}(j)$ is implemented by calling $N.\text{append}(T.\text{insert}(j))$

Taking into account all components used to implement our original dynamic function $Z$, we get the bounds of our lemma.

4.2 The algorithm

The steps of our algorithm to compute $RLBWT^+(\overline{T})$ from $LZ77(T)$ are the following:

1. sort $\mathcal{D} = \{\pi \mid \langle \pi, \lambda, c \rangle \in LZ77(T) \land \pi \neq \perp\}$;
2. process $\langle \pi_v, \lambda_v, c_v \rangle_{v=1,\ldots,z}$ from the first to last triple as follows. When processing $\langle \pi_v, \lambda_v, c_v \rangle$:
   a. use our dynamic function $Z$ to convert text position $\pi_v$ to RLBWT position $j' = Z(\pi_v)$
   b. extract $\lambda_v$ characters from RLBWT starting from position $j'$ by using the LF function; at the same time, extend RLBWT with the extracted characters.
   c. when inserting a character at position $j$ of the RLBWT, if $j$ corresponds to some text position $i \in \mathcal{D}$, then update $Z$ accordingly by setting $Z(i) \leftarrow j$. If, instead, $j$ does not correspond to any text position in $\mathcal{D}$, execute $Z.\text{expand}(j)$.

Our algorithm is outlined below as Algorithm 1. Note that the pseudocode describes all 3 steps reported at the beginning of Section 4 (steps 2 and 3 are implicit in Line 26). Follows a detailed description of the pseudocode and a result stating its complexity.

In Lines 1–5 we initialize all structures and variables. In order: we compute and sort set $\mathcal{D}$ of phrase sources, we initialize current text position $i$ ($i$ is the position of the character to be read), we initialize an empty RLBWT data structure (we will build $RLBWT^+(\overline{T})$ online), and we create an empty dynamic function data structure $Z$. In Line 6 we enter the main loop iterating over $LZ77$ factors. If the current phrase’s source is not empty (i.e. if the phrase copies a previous portion of the text), we need to extract $\lambda_v$ characters from the RLBWT. First, in Line 8 we retrieve the RLBWT position $j'$ corresponding to text position $\pi_v$ with a map query on $Z$. Note that, if $\pi_v \neq \perp$, then $i > \pi_v$ and therefore $Z(\pi_v)$ is defined (see next). We are ready to extract characters from RLBWT. For $\lambda_v$ times, we repeat the following procedure (Lines 10–19). We read the $l$-th character from the source of the $v$-th phrase (Line 10) and insert it in the RLBWT (Line 11). Importantly, the extend operation at Line 11 returns the RLBWT position $j$ at which the new character is inserted; RLBWT position $j$ correspond to text position $i$. We now have to check if $i$ is the source of some LZ77 phrase. If this is the case (Line 12), then we link text position $i$ to RLBWT position $j$ by calling a assign query on $Z$ (Line 13). If, on the other hand, $i$ is not the source of any phrase, then we call a expand query on $Z$ on the codomain element $j$. Note that, after the extend query at Line 11, RLBWT positions after the $j$-th are shifted by one. If $j'$ is one of such positions, then we increment it (Line 17). Finally, we increment text position $i$ (Line 19). At this point, we finished copying characters from the $v$-th phrase’s source (or we did not do anything if the $v$-th phrase consists of only one character). We therefore extend the RLBWT with the $v$-th trailing character (Line 20), and (as done before) associate text position $i$ to RLBWT position $j$ if $i$ is the source of some phrase (Lines 21–24). We conclude the main loop by incrementing the current position $i$ on the text (Line 25). Once all characters have been extracted from LZ77, RLBWT is a run-length BWT structure on
From LZ77 to the Run-Length Encoded Burrows-Wheeler Transform, and Back

Algorithm 1: lz77_to_rlbwt\((\langle \pi_v, \lambda_v, c_v \rangle_{v=1}^{z=\ldots})\)

\begin{algorithm}
\textbf{input}: LZ77 factorization \(LZ77(T) = \langle \pi_v, \lambda_v, c_v \rangle_{v=1}^{z=\ldots}\) of a text \(T\)
\textbf{output}: RLBWT representation \(\langle \lambda_v, c_v \rangle_{v=1}^{r=\ldots}\) of \(T\)

\begin{enumerate}
\item \(D \leftarrow \{\pi | \langle \pi, \lambda, c \rangle \in LZ77(T) \land \pi \neq \perp\}\); /* Phrase sources */
\item sort\((D)\); /* Sort phrase sources */
\item \(i \leftarrow 0;\) /* Current position on \(T\) */
\item \(RLBWT \leftarrow \epsilon;\) /* Init empty RLBWT of reversed text */
\item \(Z \leftarrow \emptyset;\) /* Init empty dynamic function structure */
\item for \(v = 1, \ldots, z\) do
\item \hspace{1em} if \(\pi_v \neq \perp\) then
\item \hspace{2em} \(j' \leftarrow Z(\pi_v);\) /* Map text position to RLBWT position */
\item \hspace{3em} for \(l = 1, \ldots, \lambda_v\) do
\item \hspace{4em} \(c \leftarrow RLBWT[j'];\) /* read char from source */
\item \hspace{5em} \(j \leftarrow RLBWT.extend(c);\) /* left-extend reverse text’s RLBWT */
\item \hspace{6em} if \(i \in D\) then
\item \hspace{7em} \(Z(i) \leftarrow j;\) /* \(j\) is the image of \(i\) */
\item \hspace{7em} else
\item \hspace{8em} \(Z.expand(j);\) /* \(j\) does not have counter-image */
\item \hspace{6em} if \(j \leq j'\) then
\item \hspace{7em} \(j' \leftarrow j' + 1;\) /* new char falls before \(j'\) */
\item \hspace{7em} \(j' \leftarrow RLBWT.LF(j');\)
\item \hspace{7em} \(i \leftarrow i + 1;\) /* Advance text position */
\item \hspace{6em} \(j \leftarrow RLBWT.extend(c_v);\) /* Extend with trailing character */
\item \hspace{6em} if \(i \in D\) then
\item \hspace{7em} \(Z(i) \leftarrow j;\)
\item \hspace{7em} else
\item \hspace{8em} \(Z.expand(j);\)
\item \hspace{7em} \(i \leftarrow i + 1;\) /* Advance text position */
\item \hspace{5em} return reverse\((RLBWT);\) /* Build and return RLBWT\((T)\) */
\end{enumerate}
\end{algorithm}

\(\hat{T}\). At Line 26 we convert it to \(RLBWT^+\(T\)\) (see previous section) and return it as a series of pairs \(\langle \lambda_v, c_v \rangle_{v=1}^{r=\ldots}\).

\textbf{Theorem 7.} Algorithm 1 converts \(LZ77(T) \rightarrow RLBWT(T)\) in \(O(n(\log r + \log z))\) time and \(O(r + z)\) words of working space.

\textbf{Proof.} Sorting set \(D\) takes \(O(z \log z) \subseteq O(n \log z)\) time. Overall, we perform \(O(z)\) map/assign and \(n\) expand queries on \(Z\). All these operations take globally \(O(n \log z)\) time. We use the structure of Theorem 3 to implement \(RLBWT^+\(T\)\) and \(RLBWT^+\(\hat{T}\)\). We perform \(n\) access, extend, and LF queries on \(RLBWT^+\(\hat{T}\)\). This takes overall \(O(n \log r)\) time. Finally, inverting \(RLBWT^+\(\hat{T}\)\) at Line 26 takes \(O(n \log r)\) time and \(O(r)\) words of space (see previous section). We keep in memory the following structures: \(D, Z, RLBWT^+\(\hat{T}\)\), and \(RLBWT^+\(T\)\). The bounds of our theorem easily follow.
Conclusions

In this paper we presented space-efficient algorithms converting between two compressed file representations – the run-length Burrows-Wheeler transform (RLBWT) and the Lempel-Ziv 77 parsing (LZ77) – using a working space proportional to the input and the output. Both representations can be significantly (up to exponentially) smaller than the text; our solutions are therefore particularly useful in those cases in which the text does not fit in main memory but its compressed representation does. Another application of the results discussed in this paper is the optimal-space construction of compressed self-indexes based on these compression techniques (e.g. [3]) taking as input the RLBWT/LZ77 compressed file.

We point out two possible developments of our ideas. First of all, our algorithms rely heavily on dynamic data structures. On the experimental side, it has been shown (see, e.g., [11]) that algorithms based on compressed dynamic strings can be hundreds of times slower than others not making use of dynamism (despite offering very similar theoretical guarantees). This is due to factors ranging from cache misses to memory fragmentation; dynamic structures inherently incur into these problems as they need to perform a large number of memory allocations and de-allocations. A possible strategy for overcoming these difficulties could be to build the RLBWT by merging two static RLBWTs while using a working space proportional to the output size. A second improvement over our results concerns theoretical running times. We note that our algorithms perform a number of steps proportional to the size \( n \) of the text. Considering that the compressed file could be exponentially smaller than the text, it is natural to ask whether it is possible to perform the same tasks in a time proportional to \( r + z \). This seems to be a much more difficult goal due to the intrinsic differences among the two compressors – one is based on suffix sorting, while the other on replacement of repetitions with pointers.

Abstract

Given two positions $i$ and $j$ in a string $T$ of length $N$, a longest common extension (LCE) query asks for the length of the longest common prefix between suffixes beginning at $i$ and $j$. A compressed LCE data structure stores $T$ in a compressed form while supporting fast LCE queries. In this article we show that the recompression technique is a powerful tool for compressed LCE data structures. We present a new compressed LCE data structure of size $O(z \lg(N/z))$ that supports LCE queries in $O(\lg N)$ time, where $z$ is the size of Lempel-Ziv 77 factorization without self-reference of $T$. Given $T$ as an uncompressed form, we show how to build our data structure in $O(N)$ time and space. Given $T$ as a grammar compressed form, i.e., a straight-line program of size $n$ generating $T$, we show how to build our data structure in $O(n \lg(N/n))$ time and $O(n + z \lg(N/z))$ space. Our algorithms are deterministic and always return correct answers.

1 Introduction

Given two positions $i$ and $j$ in a text $T$ of length $N$, a longest common extension (LCE) query LCE$(i,j)$ asks for the length of the longest common prefix between suffixes beginning at $i$ and $j$. Since LCE queries play a central role in many string processing algorithms (see text book [6] for example), efficient LCE data structures have been extensively studied. If we are allowed to use $O(N)$ space, optimal $O(1)$ query time can be achieved by, e.g., lowest common ancestor queries [1] on the suffix tree of $T$. However, $O(N)$ space can be too expensive nowadays as the size of strings to be processed becomes quite large. Thus, recent studies focus on more space efficient solutions.

Roughly there are three scenarios: Several authors have studied tradeoffs among query time, construction time and data structure size [19, 5, 4, 21]: In [18], Prezza presented in-place LCE data structures showing that the memory space for storing $T$ can be replaced with an LCE data structure while retaining optimal substring extraction time; LCE data structures working on grammar compressed representation of $T$ were studied in [7, 3, 2, 17].

In this article we pursue the third scenario, which is advantageous when $T$ is highly compressible. In grammar compression, $T$ is represented by a Context Free Grammar (CFG) that generates $T$ and only $T$. In particular CFGs in Chomsky normal form, called Straight Line Programs (SLPs), are often considered as any CFG can be easily transformed into an SLP without changing the order of grammar size. Let $S$ be an arbitrary SLP of size $n$ generating $T$. Bille et al. [2] showed a Monte Carlo randomized data structure of $O(n)$ space that supports LCE queries in $O(\lg N + \lg^2 \ell)$ time, where $\ell$ is the answer to the LCE query.

* I was supported by JSPS KAKENHI Grant Number 16K16009.
Because their algorithm is based on Karp-Rabin fingerprints, the answer is correct w.h.p (with high probability). If we always expect correct answers, we have to verify fingerprints in preprocessing phase, spending either \( O(N \log N) \) time (w.h.p.) and \( O(N) \) space or \( O(\frac{N^2}{z} \log N) \) time (w.h.p.) and \( O(n) \) space.

For a deterministic solution, I et al. [7] proposed an \( O(n^2) \)-space data structure, which can be built in \( O(n^2h) \) time and \( O(n^2) \) space from \( S \), and supports LCE queries in \( O(h \log N) \) time, where \( h \) is the height of \( S \). As will be stated in Theorem 2, we outstrip this result.

Our work is most similar to that presented in [17]. They showed that the signature encoding [15] of \( T \), a special kind of CFGs that can be stored in \( O(z \log N \log^* N) \) space, can support LCE queries in \( O(\log N + \log \ell \log^* N) \) time, where \( z \) is the size of LZ77 factorization\(^1\) of \( T \) and \( \log^* \) is the iterated logarithm. The signature encoding is based on the locally consistent parsing technique, which determines the parsing of a string by local surrounding. A key property of the signature encoding is that any occurrence of the same substring of length \( \ell \) in \( T \) is guaranteed to be compressed in almost the same way leaving only \( O(\log \ell \log^* N) \) discrepancies in its surrounding. As a result, an LCE query can be answered by tracing the \( O(\log \ell \log^* N) \) surroundings created over two occurrences of the longest common extension. Since the cost \( O(\log N) \) is needed anyway to traverse the derivation tree of height \( O(\log N) \) from the root, an LCE query is supported in \( O(\log N + \log \ell \log^* N) \) time.

In this article we show that CFGs created by the recompression technique exhibit a similar property that can be used to answer LCE queries in \( O(\log N) \) time. In recent years recompression has been proved to be a powerful tool in problems related to grammar compression [8, 9, 10, 13] and word equations [11, 12]. The main component of recompression is to replace some pairs in a string with variables of the CFG. Although we use global information (like the frequencies of pairs in the string) to determine which pairs to be replaced, the pairing itself is done very locally, i.e., “all” occurrences of the pairs are replaced regardless of contexts. Then we can show that recompression compresses any occurrence of the same substring in \( T \) in almost the same way leaving only \( O(\log N) \) discrepancies in its surrounding. This leads to an \( O(\log N) \)-time algorithm to answer LCE queries, improving the \( O(\log N + \log \ell \log^* N) \)-time algorithm of [17]. We also improve the data structure size from \( O\big(z \log N \log^* N\big) \) of [17]\(^2\) to \( O\big(z \log(N/z)\big) \).

In [17], the authors proposed efficient algorithms to build their LCE data structure from various kinds of input as summarized in Table 1. We achieve a better and cleaner complexity to build our LCE data structure from SLPs. This has a great impact on compressed string processing, in which we are to solve problems on SLPs without decompressing the string explicitly. For instance, we can apply our result to the problems discussed in Section 7 of [17] and immediately improve the results (other than Theorem 17). It should be noted that the data structures in [17] also support efficient text edit operations. We are not sure if our data structures can be efficiently dynamized.

Theorems 1 and 2 show our main results. Note that our data structure is a simple CFG of height \( O(\log N) \) on which we can simulate the traversal of the derivation tree in constant time per move. Thus, it naturally supports Extract\((i, \ell)\) queries, which asks for retrieving the substring \( T[i..i + \ell - 1] \), in \( O(\log N + \ell) \) time.

\(^1\) Note that there are several variants of LZ77 factorization. In this article we refer to the one that is known as the \( f \)-factorization without self-reference as LZ77 factorization unless otherwise noted.

\(^2\) We believe that the space complexities of [17] can be improved to \( O(z \log(N/z) \log^* N) \) by using the same trick we use in Lemma 13.
Table 1 Comparison of construction time and space between ours and [17], where $N$ is the length of $T$, $S$ is an SLP of size $n$ generating $T$, $z$ is the size of LZ77 factorization of $T$, and $f_A$ is the time needed for predecessor queries on a set of $z \log N \log^* N$ integers from an $N$-element universe.

Theorem 1. Given a string $T$ of length $N$, we can compute in $O(N)$ time and space a compressed representation of $T$ of size $O(z \log(N/z))$ that supports Extract$(i, \ell)$ in $O(\log N + \ell)$ time and LCE queries in $O(\log N)$ time.

Theorem 2. Given an SLP of size $n$ generating a string $T$ of length $N$, we can compute in $O(n \log(N/n))$ time and $O(n + z \log(N/z))$ space a compressed representation of $T$ of size $O(z \log(N/z))$ that supports Extract$(i, \ell)$ in $O(\log N + \ell)$ time and LCE queries in $O(\log N)$ time.

Suppose that we are given the LZ77-compression of size $z$ of $T$ as an input. Since we can convert the input into an SLP of size $O(z \log(N/z))$ [20], we can apply Theorem 2 to the SLP and get the next corollary.

Corollary 3. Given the LZ77-compression of size $z$ of a string $T$ of length $N$, we can compute in $O(z \log^2(N/z))$ time and $O(z \log(N/z))$ space a compressed representation of $T$ of size $O(z \log(N/z))$ that supports Extract$(i, \ell)$ in $O(\log N + \ell)$ time and LCE queries in $O(\log N)$ time.

Technically, this work owes very much to two papers [10, 9]. For instance, our construction algorithm of Theorem 1 is essentially the same as the grammar compression algorithm [10], which produces an SLP of size $O(g^* \log(N/g^*))$, where $g^*$ is the smallest grammar size to generate $T$. Our contribution is in discovering the above mentioned property that can be used for fast LCE queries. Also, we use the property to upper bound the size of our data structure in terms of $z$ rather than $g^*$. Since it is known that $z \leq g^*$ holds [20], an upper bound in terms of $z$ is preferable. The technical issues in our construction algorithm of Theorem 2 have been tackled in [9], in which the recompression technique is used to solve the fully-compressed pattern matching problems. However, we make some contributions on top of it: We give a new observation that simplifies the implementation and analysis of a component of recompression called BComp (see Section 4.1.2). Also, we achieve a better construction time $O(n \log(N/n))$ than what we obtain by straightforwardly applying the analysis in [9]—$O(n \log N)$.

2 Preliminaries

An alphabet $\Sigma$ is a set of characters. A string over $\Sigma$ is an element in $\Sigma^*$. For any string $w \in \Sigma^*$, $|w|$ denotes the length of $w$. Let $\varepsilon$ be the empty string, i.e., $|\varepsilon| = 0$. Let $\Sigma^+ = \Sigma^* \setminus \{\varepsilon\}$.

For any $1 \leq i \leq |w|$, $w[i]$ denotes the $i$-th character of $w$. For any $1 \leq i \leq j \leq |w|$, $w[i..j]$
denotes the substring of $w$ beginning at $i$ and ending at $j$. For convenience, let $w[i..j] = \varepsilon$ if $i > j$. For any $0 \leq i \leq |w|$, $w[1..i]$ (resp. $w[i+1..|w|]$) is called the prefix (resp. suffix) of $w$ of length $i$. We say that a string $x$ occurs at position $i$ in $w$ iff $w[i..i+|x|-1] = x$. A substring $w[i..j] = c^d$ ($c \in \Sigma, d \geq 1$) of $w$ is called a block iff it is a maximal run of a single character, i.e., $(i = 1 \lor w[i-1] \neq c) \land (j = |w| \lor w[j+1] \neq c)$.

The text on which LCE queries are performed is denoted by $T \in \Sigma^*$ with $N = |T|$ throughout this paper. We assume that $\Sigma$ is an integer alphabet $[1..N^{O(1)}]$ and the standard word RAM model with word size $\Omega(\lg N)$.

The size of our compressed LCE data structure is bounded by $O(z \lg(N/z))$, where $z$ is the size of the LZ77 factorization of $T$ defined as follows:

**Definition 4 (LZ77 factorization).** The factorization $T = f_1 f_2 \cdots f_z$ is the LZ77 factorization of $T$ iff the following condition holds: For any $1 \leq i \leq z$, let $p_i = |f_1 f_2 \cdots f_{i-1}| + 1$, then $f_i = T[p_i]$ if $T[p_i]$ does not appear in $T[1..p_i-1]$, otherwise $f_i$ is the longest prefix of $T[p_i..N]$ that occurs in $T[1..p_i-1]$.

In this article, we deal with grammar compressed strings, in which a string is represented by a Context Free Grammar (CFG) generating the string only. In particular, we consider **Straight-Line Programs (SLPs)** that are CFGs in Chomsky normal form. Formally, an SLP that generates a string $T$ is a triple $S = (\Sigma, \mathcal{V}, \mathcal{D})$, where $\Sigma$ is the set of characters (terminals), $\mathcal{V}$ is the set of variables (non-terminals), $\mathcal{D}$ is the set of deterministic production rules whose righthand sides are in $\mathcal{V}^2 \cup \Sigma$, and the last variable derives $T$.

Let $n = |V|$. We treat variables as integers in $[1..n]$ (which should be distinguishable from $\Sigma$ by having extra one bit), and $\mathcal{D}$ as an injective function that maps a variable to its righthand side. We assume that given any variable $X$ we can access in $O(1)$ time the information on $X$, e.g., $\mathcal{D}(X)$. We refer to $n$ as the size of $\mathcal{S}$ since $\mathcal{S}$ can be encoded in $O(n)$ space. Note that $N$ can be as large as $2^n - 1$, and so, SLPs have a potential to achieve exponential compression.

We extend SLPs by allowing run-length encoded rules whose righthand sides are of the form $X^d$ with $X \in \mathcal{V}$ and $d \geq 2$, and call such CFGs **run-length SLPs (RLSLPs)**. Since a run-length encoded rule can be stored in $O(1)$ space, we still define the size of an RLSLP by the number of variables.

Let us consider the derivation tree $T$ of an RLSLP $S$ that generates a string $T$, where we delete all the nodes labeled with terminals for simplicity. That is, every node in $T$ is labeled with a variable. The height of $S$ is the height of $T$. We say that a sequence $C = v_1 \cdots v_m$ of nodes is a chain iff the nodes are all adjacent in this order, i.e., the beginning position of $v_{i+1}$ is the ending position of $v_i$ plus one for any $1 \leq i < m$. $C$ is labeled with the sequence of labels of $v_1 \cdots v_m$. For any sequence $p \in \mathcal{V}^*$ of variables, let $val_S(p)$ denote the string obtained by concatenating the strings derived from all variables in the sequence. We omit $S$ when it is clear from context. We say that $p$ generates $val(p)$. Also, we say that $p$ occurs at position $i$ iff there is a chain that is labeled with $p$ and begins at $i$.

The next lemma, which is somewhat standard for SLPs, also holds for RLSLPs.

**Lemma 5.** For any RLSLP $S$ of height $h$ generating $T$, by storing $|val(X)|$ for every variable $X$, we can extract $val(i, \ell)$ in $O(h + \ell)$ time.

---

3 We treat the last variable as the starting variable.
3 LCE data structure built from uncompressed texts

In this section, we prove Theorem 1 by showing that the RLSLP obtained by grammar compression algorithm [9] based on recompression can be used for fast LCE queries. In Subsection 3.1 we review recompression and introduce notation we use. In Subsection 3.2 we present a new characterization of recompression, which is a key to our contributions.

3.1 TtoG: Grammar compression based on recompression

In [9] Jeż proposed an algorithm TtoG to compute an RLSLP of $T$ in $O(N)$ time.\footnote{Indeed, the paper shows how to compute an “SLP” of size $O(\lg(N/g^*))$, where $g^*$ is the smallest SLP size to generate $T$. In order to estimate the number of SLP’s variables needed to represent run-length encoded rules, its analysis becomes much involved.} Let $TtoG(T)$ denote the RLSLP of $T$ produced by TtoG. We use the term letters for variables introduced by TtoG. In particular, we often refer to an occurrence of a sequence of letters, for which the readers should recall the definition of an occurrence of a sequence of variables. Also, we use $c$ (rather than $X$) to represent a letter.

TtoG consists of two different types of compression, BComp and PComp, which stand for Block Compression and Pair Compression, respectively.

- BComp: Given a string $w$ over $\Sigma = [1..|w|]$, BComp compresses $w$ by replacing all blocks of length $\geq 2$ with fresh letters. Note that BComp eliminates all blocks of length $\geq 2$ in $w$. We can conduct BComp in $O(|w|)$ time and space (Lemma 6).

- PComp: Given a string $w$ over $\Sigma = [1..|w|]$ that contains no block of length $\geq 2$, PComp compresses $w$ by replacing all pairs from $\Sigma \Sigma$ with fresh letters, where $(\Sigma, \hat{\Sigma})$ is a partition of $\Sigma$. i.e., $\Sigma = \Sigma \cup \hat{\Sigma}$ and $\Sigma \cap \hat{\Sigma} = \emptyset$. We can deterministically compute in $O(|w|)$ time and space a partition of $\Sigma$ by which at least $(|w| - 1)/4$ pairs are replaced (Lemma 7), and conduct PComp in $O(|w|)$ time and space (Lemma 8).

Let $T_0$ be a sequence of letters obtained by replacing every character $c$ of $T$ with a letter generating $c$. TtoG compresses $T_0$ by applying BComp and PComp by turns until the string gets shrunk into a single letter. Since PComp compresses a given string by a constant factor $3/4$, the height of $TtoG(T)$ is $O(\lg N)$, and the total running time is bounded by $O(N)$.

In order to give a formal description we introduce some notation below. TtoG transforms level by level $T_0$ into strings, $T_1, T_2, \ldots, T_h$, where $|T_h| = 1$. For any $0 \leq h \leq \hat{h}$, we say that $h$ is the level of $T_h$. If $h$ is even, the transformation from $T_h$ to $T_{h+1}$ is performed by BComp, and production rules of the form $c \rightarrow \hat{c}d$ are introduced. If $h$ is odd, the transformation from $T_h$ to $T_{h+1}$ is performed by PComp, and production rules of the form $c \rightarrow \hat{c}\hat{c}$ are introduced. Let $\Sigma_h$ be the set of letters appearing in $T_h$. For any even $h$ $(0 \leq h < \hat{h})$, let $\hat{\Sigma}_h$ denote the set of letters with which there is a block of length $\geq 2$ in $T_h$. For any odd $h$ $(0 \leq h < \hat{h})$, let $(\Sigma_h, \hat{\Sigma}_h)$ denote the partition of $\Sigma_h$ used in PComp of level $h$.

Figure 1 shows an example of how TtoG compresses $T_0$.

The following four lemmas show how to conduct BComp, PComp, and thus, TtoG, efficiently, which are essentially the same as respectively Lemma 2, Lemma 5, Lemma 6, and Theorem 1, stated in [9]. We give the proofs in Appendix for the sake of completeness.

\textbf{Lemma 6.} Given a string $w$ over $\Sigma = [1..|w|]$, we can conduct BComp in $O(|w|)$ time and space.

For any string $w \in \Sigma^*$ that contains no block of length $\geq 2$, let $\text{Freq}_w(c, \hat{c}, 0)$ (resp. $\text{Freq}_w(c, \hat{c}, 1)$) with $c > \hat{c} \in \Sigma$ denote the number of occurrences of $c\hat{c}$ (resp. $\hat{c}c$) in $w$. We

**Figure 1** An example of how TtoG compresses $T_0$. Below we enumerate non-empty $\Sigma_1$, $\Sigma_2$, $\Sigma_3$ and production rules introduced in each level. From $T_0$ to $T_1$: $\Sigma_0 = \{1, 2, 4\}$, $\{5 \to 1\}$, $\{7 \to 2\}$, $\{8 \to 4\}$. From $T_1$ to $T_2$: $\Sigma_1 = \{1, 3, 5, 6, 7\}$, $\Sigma_2 = \{2, 4, 8\}$, $\{9 \to 1\}$, $\{10 \to 3\}$, $\{11 \to 3\}$, $\{12 \to 5\}$, $\{13 \to 6\}$. From $T_2$ to $T_3$: $\Sigma_2 = \{9\}$, $\{14 \to 9\}$. From $T_3$ to $T_4$: $\Sigma_3 = \{3, 7, 12, 13\}$, $\Sigma_4 = \{10, 14\}$, $\{15 \to 7\}$, $\{16 \to 12\}$, $\{17 \to 13\}$. From $T_4$ to $T_5$: $\Sigma_5 = \{3, 10, 11, 16, 17\}$, $\Sigma_6 = \{15\}$, $\{18 \to 16\}$, $\{19 \to 17\}$. From $T_5$ to $T_6$: $\Sigma_7 = \{3, 10, 11\}$, $\Sigma_8 = \{18, 19\}$, $\{20 \to 3\}$, $\{21 \to 10\}$. From $T_6$ to $T_7$: $\Sigma_9 = \{11, 20\}$, $\Sigma_9 = \{21\}$, $\{22 \to 20\}$. From $T_7$ to $T_8$: $\Sigma_{11} = \{22\}$, $\Sigma_{11} = \{11\}$, $\{23 \to 22\}$. From $T_8$ to $T_9$: $\Sigma_{12} = \{22\}$. From $T_9$ to $T_{10}$: $\Sigma_{10} = \{11\}$.

refer to the list of non-zero $\text{Freq}_w(c, \tilde{e}, \cdot)$ sorted in increasing order of $c$ as the adjacency list of $w$. Note that it is a representation of the weighted directed graph in which there are exactly $\text{Freq}_w(c, \tilde{e}, 0)$ (resp. $\text{Freq}_w(c, \tilde{e}, 1)$) edges from $c$ to $\tilde{e}$ (resp. from $\tilde{e}$ to $e$). Each occurrence of a pair in $w$ is counted exactly once in the adjacency list. Then the problem of computing a good partition $(\Sigma(\Sigma))$ of $\Sigma$ reduces to maximum directed cut problem on the graph. Algorithm 1 is based on a simple greedy 1/4-approximation algorithm of maximum directed cut problem.

**Lemma 7.** Given the adjacency list of size $m$ of a string $w \in \Sigma^*$, Algorithm 1 computes in $O(m)$ time a partition $(\Sigma, \Sigma)$ of $\Sigma$ such that the number of occurrences of pairs from $\Sigma(\Sigma)$ in $w$ is at least $(|w| - 1)/4$.

**Lemma 8.** Given a string $w$ over $\Sigma = [1..|w|]$ that contains no block of length $\geq 2$, we can conduct PComp in $O(|w|)$ time and space.

**Lemma 9.** Given a string $T$ over $\Sigma = [1..N^{O(1)}]$, we can compute TtoG($T$) in $O(N)$ time and space.

### 3.2 Popped sequences

We give a new characterization of recombination, which is a key to fast LCE queries as well as obtaining the upper bound $O(\lg(N/w))$ for the size of TtoG($T$). For any substring $w$ of $T$, we define the Popped Sequence ($PSeq$), denoted by $PSeq(w)$, of $w$ (formal definition is in the next paragraph). $PSeq(w)$ is a sequence of letters such that $\text{val}(PSeq(w)) = w$ and consists of $O(\lg N)$ blocks of letters. It is not surprising that any substring can be represented by $O(\lg N)$ blocks of letters because the height of TtoG($T$) is $O(\lg N)$. The significant property of $PSeq(w)$ is that it occurs at “every” occurrence of $w$. A similar property has been observed in CFGs produced by locally consistent parsing and utilized for compressed indexes [14, 16].
We iterate this until the string disappears. 

\[ PSeq(w) \] is the sequence obtained by concatenating the popped-out letters/blocks in an appropriate order, i.e., the order of the positions they occur. Note that for any occurrence of \( w \) the letters are compressed in the same way at least until they are popped out. Hence \( w_h \) is created for every occurrence of \( w \) and the occurrence of \( PSeq(w) \) is guaranteed (see also Figure 2).

\[ \text{Algorithm 1: How to compute a partition of } \Sigma \text{ for } PComp \text{ to compress } w \text{ by } 3/4. \]

**Input:** Adjacency list of \( w \in \Sigma^* \).

**Output:** \((\hat{\Sigma}, \hat{\Sigma})\) s.t. \# occurrences of pairs from \( \hat{\Sigma} \hat{\Sigma} \) in \( w \) is at least \((|w| - 1)/4\).

// The information whether \( c \in \Sigma \) is in \( \hat{\Sigma} \) or \( \Sigma \) is written in the data space for \( c \), which can be accessed in \( O(1) \) time. */

1. \( \hat{\Sigma} \leftarrow \Sigma \leftarrow \emptyset \);

and a dynamic compressed LCE data structure [17]. For example, in [16, 17] the sequence having such a property is called the common sequence of \( w \) but its representation size is \( O(|\lg |w||\lg ^* N|) \) rather than \( O(|\lg N|) \).

\( PSeq(w) \) is the sequence of letters characterized by the following procedure. Let \( w_0 \) be the substring of \( T_0 \) that generates \( w \). We consider applying BComp and PComp to \( w_0 \) exactly as we did to \( T \) but in each level we pop some letters out from both ends if the letters can be coupled with letters outside the scope. Formally, in increasing order of \( h \geq 0 \), we get \( w_{h+1} \) from \( w_h \) as follows:

- If \( h \) is even. We first pop out the leftmost and rightmost blocks of \( w_h \) if they are blocks of letter \( c \in \hat{\Sigma}_h \). Then we get \( w_{h+1} \) by applying BComp to the remaining string.

- If \( h \) is odd. We first pop out the leftmost letter and rightmost letter of \( w_h \) if they are letters in \( \hat{\Sigma}_h \) and \( \hat{\Sigma}_h \), respectively. Then we get \( w_{h+1} \) by applying PComp to the remaining string.

We iterate this until the string disappears. \( PSeq(w) \) is the sequence obtained by concatenating the popped-out letters/blocks in an appropriate order, i.e., the order of the positions they occur. Note that for any occurrence of \( w \) the letters are compressed in the same way at least until they are popped out. Hence \( w_h \) is created for every occurrence of \( w \) and the occurrence of \( PSeq(w) \) is guaranteed (see also Figure 2).
The next lemma formalizes the above discussion.

**Lemma 10.** For any substring \( w \) of \( T \), \( PSeq(w) \) consists of \( O(\frac{\lg N}{h}) \) blocks of letters. In addition, \( w \) occurs at position \( i \) iff \( PSeq(w) \) occurs at \( i \).

The next lemma and corollary are used to prove Lemmas 13 and 14.

**Lemma 11.** For any chain \( C \) whose label consists of \( m \) blocks of letters, the number of ancestor nodes of \( C \) is \( O(m) \).

**Corollary 12.** For any chain \( C \) corresponding to \( PSeq(T[b..e]) \) for some interval \( [b..e] \), the number of ancestor nodes of \( C \) is \( O(\lg N) \).

**Lemma 13.** The size of \( TtoG(T) \) is \( O(z \lg(N/z)) \).

**Proof.** We first show the bound \( O(z \lg N) \) and later improve the analysis to \( O(z \lg(N/z)) \).

Let \( f_1 \ldots f_k \) be the LZ77 factorization of \( T \). For any \( 1 \leq i \leq z \), let \( L_i \) be the set of letters used in the ancestor nodes of leaves corresponding to the prefix \( f_1 f_2 \ldots f_i \). Clearly \( |L_1| = O(\lg N) \). For any \( 1 < i \leq z \), we estimate \( |L_i \setminus L_{i-1}| \). Since \( f_i \) occurs in \( f_1 \ldots f_{i-1} \), we can see that the letters of \( PSeq(f_i) \) are in \( L_{i-1} \) thanks to Lemma 10. Let \( C_i \) be the chain corresponding to the occurrence \( \{f_1 \ldots f_{i-1} + 1\} \) of \( PSeq(f_i) \). Then, the letters in \( L_i \setminus L_{i-1} \) are only in the labels of ancestor nodes of \( C_i \). Since \( PSeq(f_i) \) consists of \( O(\lg N) \) blocks of letters, \( |L_i \setminus L_{i-1}| \) is bounded by \( O(\lg N) \) due to Lemma 11. Therefore the size of \( TtoG(T) \) is \( \sum_{i=1}^{h} |L_i \setminus L_{i-1}| = O(z \lg N) \).

In order to improve the bound to \( O(z \lg(N/z)) \), we employ the same trick that was used in [20, 9]. Let \( h = 2 \log_{3/4} (N/z) = 2 \log_{3/4} (z/N) \). Recall that \( PComp \) compresses a given string by a constant factor \( 3/4 \). Since \( PComp \) has been applied \( h/2 \) times until the level \( h \), \( |T_h| \leq N(3/4)^{N/2} = z \), and hence, the number of letters introduced in level \( \geq h \) is bounded by \( O(z) \). Then, we can ignore all the letters introduced in level \( \geq h \) in the analysis of the previous paragraph, and by doing so, the bound \( O(\lg N) \) of \( |L_i \setminus L_{i-1}| \) is improved to \( O(h) = O(\lg(N/z)) \). This yields the bound \( O(z \lg(N/z)) \) for the size of \( TtoG(T) \).

**Lemma 14.** Given \( TtoG(T) \), we can answer \( \text{LCES}(i, j) \) in \( O(\lg N) \) time.

**Proof.** We compute \( \text{LCES}(i, j) \) by matching the common sequence of letters occurring at \( i \) and \( j \) from left to right. First we traverse the derivation tree of \( TtoG(T) \) from the root down to the \( i \)-th and \( j \)-th leaves simultaneously while seeking the common block occurring at \( i \) and \( j \). If there is no such block, \( \text{LCES}(i, j) = 0 \), and we are done. Otherwise we stop at some internal nodes that contain the common block in their children. Let \( \ell_1 \) be the length of the string generated by the block. Because \( \text{LCES}(i, j) \geq \ell_1 \), we move on matching the next block by (possibly traversing up first and) traversing down to the \( (i + \ell_1) \)-th and \( (j + \ell_1) \)-th leaves. We iterate this procedure until we find no further common block. Then \( \text{LCES}(i, j) = \sum_{k=1}^{m} \ell_k \), where \( \ell_1, \ell_2, \ldots, \ell_m \) is the sequence of lengths of the common blocks we found.

Now we show that the above described algorithm runs in \( O(\lg N) \) time. Note that it is bounded by the number of nodes we visit during the computation. In the light of Lemma 10, \( PSeq(w) \) occurs at both \( i \) and \( j \), where \( w \) is the longest common prefix of two suffixes beginning at \( i \) and \( j \). Let \( C_i \) (resp. \( C_j \)) be the chain that is labeled with \( PSeq(w) \) and begins at \( i \) (resp. \( j \)). Since the algorithm matches \( PSeq(w) \) or a succincter common sequence existing above \( C_i \) and \( C_j \), we never go down below the parents of \( C_i \) or \( C_j \) during the computation. Hence, the number of visited nodes is bounded by the number of nodes that are ancestors of \( C_i \) or \( C_j \), which is \( O(\lg N) \) by Corollary 12.

Theorem 1 is immediately from Lemmas 9, 5 and 14.
4 LCE data structure built from SLPs

In this section, we prove Theorem 2. Input is now an arbitrary SLP \( S = (\Sigma, V, D) \) of size \( n \) generating \( T \). Basically what we consider is to simulate \( \text{TtoG} \) on \( S \), namely, compute \( \text{TtoG}(T) \) without decompressing \( S \) explicitly. In Section 4.1, we present an algorithm \( \text{SimTtoG} \) that simulates \( \text{TtoG} \) in \( O(n \log^2(N/n)) \) time and \( O(n + z \log(N/z)) \) space. In Section 4.2, we present how to modify \( \text{SimTtoG} \) to get Theorem 2.

4.1 SimTtoG: Simulating TtoG on CFGs

We present an algorithm \( \text{SimTtoG} \) to simulate \( \text{TtoG} \) on \( S \). To begin with, we compute the CFG \( S_0 = (\Sigma_0, V, D_0) \) obtained by replacing, for all variables \( X \in V \) with \( D(X) \in \Sigma \), every occurrence of \( X \) in the right-hand sides of \( D \) with the letter generating \( D(X) \). Note that \( \Sigma_0 \) is the set of terminals of \( S_0 \), and \( S_0 \) generates \( T_0 \). \( \text{SimTtoG} \) transforms level by level \( S_0 \) into CFGs, \( S_1 = (\Sigma_1, V, D_1), S_2 = (\Sigma_2, V, D_2) \), \( \ldots \), \( S_h = (\Sigma_h, V, D_h) \), where each \( S_h \) generates \( T_h \). Namely, compression from \( T_h \) to \( T_{h+1} \) is simulated on \( S_h \). We can correctly compute the letters introduced in each level \( h + 1 \) while modifying \( S_h \) into \( S_{h+1} \), and hence, we get all the letters of \( \text{TtoG}(T) \) in the end. We note that new “variables” are never introduced and the modification is done by rewriting right-hand sides of the original variables.

Here we introduce the special formation of the CFGs \( S_h \) (it is a generalization of SLPs in a different sense from RLSLPs): For any \( X \in V \), \( D_h(X) \) consists of an “arbitrary number” of letters and at most “two” variables. More precisely, the following condition holds:

For any variable \( X \in V \) with \( D(X) = \hat{X} \hat{X} \), \( D_h(X) \) is either \( w_1 \hat{X} w_2 \hat{X} w_3, w_1 \hat{X} w_2, w_2 \hat{X} w_3 \) or \( w_1, w_2, w_3 \in \Sigma_h^* \), where \( w_1 = w_3 = \varepsilon \) if \( X \) is not the starting variable.

As opposed to SLPs and RLSLPs, we define the size of \( S_h \) by the total lengths of right-hand sides and denote it by \( |S_h| \).

4.1.1 PComp on CFGs

We firstly demonstrate that the adjacency list of \( T_h \) can be computed efficiently.

**Lemma 15** (Lemma 6.1 of [10]). For any odd \( h \) (0 ≤ \( h \) < \( h \)), the adjacency list of \( T_h \), whose size is \( O(|S_h|) \), can be computed in \( O(|S_h| + n) \) time and space.

**Proof.** For any variable \( X \in V \), let \( \text{VOcc}(X) \) denote the number of occurrences of the nodes labeled with \( X \) in the derivation tree of \( S \). It is well known that \( \text{VOcc}(X) \) for all variables can be computed in \( O(n) \) time and space on the DAG representation of the tree.\(^5\) Also, for any variable \( X \in V \), let \( \text{LML}(X) \) and \( \text{RML}(X) \) denote the leftmost letter and respectively rightmost letter of \( \text{val}_{S_h}(X) \). We can compute \( \text{LML}(X) \) for all variables in \( O(|S_h|) \) time by a bottom up computation, i.e., \( \text{LML}(X) = \text{LML}(Y) \) if \( D_h(X) \) starts with a variable \( Y \), and \( \text{LML}(X) = w[1] \) if \( D_h(X) \) starts with a non-empty string \( w \). In a completely symmetric way \( \text{RML}(X) \) can be computed in \( O(|S_h|) \) time.

Now observe that any occurrence \( i \) of a pair \( \hat{e}\hat{c} \) in \( T_h \) can be uniquely associated with a variable \( X \) that is the label of the lowest node covering the interval \([i..i+1]\) in the derivation tree of \( S_h \) (recall that \( S_h \) generates \( T_h \)). We intend to count all the occurrences of pairs associated with \( X \) in \( D_h(X) \). For example, let \( D_h(X) = \hat{X} w_2 \hat{X} \) with \( w_2 \in \Sigma_h^* \). Then \( \hat{c} \hat{e} \)

\(^5\) It is sufficient to compute \( \text{VOcc}(X) \) once at the very beginning of \( \text{SimTtoG} \).
appears explicitly in \( w_2 \) or crosses the boundaries of \( \hat{X} \) and/or \( \hat{\hat{X}} \). If \( \hat{c} \hat{c} \) crosses the boundary of \( \hat{X} \), \( RML(\hat{X}) \) is \( \hat{c} \) and \( \hat{c} \) follows, i.e., \( (w_2[1] = \hat{c}) \lor (w_2 = \varepsilon \land LML(\hat{X}) = \hat{c}) \). Using \( RML(\hat{X}) \) and \( LML(\hat{X}) \), we can compute in \( O(|D_R(\hat{X})|) \) time and space a \((|D_R(\hat{X})| - 1)\)-size multiset that lists all the explicit and crossing pairs in \( D_R(\hat{X}) \). Each pair \( \hat{c} \hat{c} \) with \( \hat{c} > \hat{c} \) (resp. \( \hat{c} < \hat{c} \)) is listed by a quadruple \((\hat{c}, \hat{c}, 0, VOcc(\hat{X}))\) (resp. \((\hat{c}, \hat{c}, 1, VOcc(\hat{X}))\)). \( VOcc(\hat{X}) \) means that the pair has a weight \( VOcc(\hat{X}) \) because the pair appears every time a node labeled with \( X \) appears in the derivation tree.

We compute such a multiset for every variable, which takes \( O(|S_h|) \) time and space in total. Next we sort the obtained list in increasing order of the first three integers in a quadruple. Note that the maximum value of letters is \( O(z \lg(N/z)) \) due to Lemma 13, and \( O(z \lg(N/z)) = O(n^2) \) since \( z \leq n \) and \( \lg N \leq n \) hold. Thus the sorting can be done in \( O(n) \) time and space by radix sort. Finally we can get the adjacency list of \( T_h \) by summing up weights of the same pair. The size of the list is clearly \( O(|S_h|) \).

The next lemma shows how to implement \( PComp \) on CFGs:

\[ \text{Lemma 16. For any odd } h \ (0 \leq h < \hat{h}), \text{ we can compute } S_{h+1} \text{ from } S_h \text{ in } O(|S_h| + n) \text{ time and space. In addition, } |S_{h+1}| \leq |S_h| + 2n. \]

\textbf{Proof.} We first compute the partition \((\hat{\Sigma}_h, \Sigma_h)\) of \( \Sigma_h \), which can be done in \( O(|S_h| + n) \) time and space by Lemmas 15 and 7.

Given \((\hat{\Sigma}_h, \Sigma_h)\), we can detect all the positions of the pairs from \( \hat{\Sigma}_h \Sigma_h \) in the righthands of \( D_h \), which are to be compressed. Some of the appearances of the pairs are explicit and the others are crossing. While explicit pairs can be compressed easily, crossing pairs need additional treatment. To deal with crossing pairs, we first uncross them by popping out every \( LML(Y) \in \hat{\Sigma}_h \) and \( RML(Y) \in \hat{\Sigma}_h \) from \( val_{S_h}(Y) \) and popping them into the appropriate positions in the other rules. More precisely, we do the followings (for technical reason, do \textit{PopInLet} first):

\textbf{PopInLet.} For any variable \( X \), if \( D_h(X)[i] = Y \in \mathcal{V} \) with \( i > 1 \) (\( i \geq 1 \) if \( X \) is the starting variable) and \( LML(Y) \in \hat{\Sigma}_h \), replace the occurrence of \( Y \) with \( LML(Y)Y \): if \( D_h(X)[i] = Y \in \mathcal{V} \) with \( i < |D_h(X)| \) (\( i \leq |D_h(X)| \) if \( X \) is the starting variable) and \( RML(Y) \in \hat{\Sigma}_h \), replace the occurrence of \( Y \) with \( Y RML(Y) \).

\textbf{PopOutLet.} For any variable \( X \) other than the starting variable, if \( D_h(X)[1] \in \hat{\Sigma}_h \), remove the first letter of \( D_h(X) \); and if \( D_h(X)[|D_h(X)|] \in \hat{\Sigma}_h \), remove the last letter of \( D_h(X) \).

In addition, if \( X \) becomes empty, we remove all the appearances of \( X \) in \( D_h \).

PopOutLet removes \( LML(Y) \in \hat{\Sigma}_h \) and \( RML(Y) \in \hat{\Sigma}_h \) from \( val_{S_h}(Y) \) (which can be a part of a crossing pair), and \textit{PopInLet} introduces the removed letters into appropriate positions in \( D_h \) so that the modified \( S_h \) keeps to generate \( T_h \). Notice that for each variable \( X \) the positions where letters popped in is at most two (four if \( X \) is the starting variable) and there is at least one variable that has no variables below, and hence, no letters popped in. Thus, the size of \( S_h \) increases at most \( 2n \). The uncrossing can be conducted in \( O(|S_h| + n) \) time.

Since all the pairs to be compressed become explicit, we can conduct \( BComp \) in \( O(|S_h| + n) \) time as follows. We scan righthand sides in \( O(|S_h|) \) time and list all the occurrences of pairs to be compressed. Each occurrence of pair \( \tilde{c} \tilde{c} \) is listed by a triple \((\tilde{c}, \tilde{c}, p)\), where \( p \) is the pointer to the occurrence. Then we sort the list according to the pair of integers \((\tilde{c}, \tilde{c})\), which can be done in \( O(|S_h| + n) \) time and space by radix sort because \( \tilde{c} \) and \( \tilde{c} \) are \( O(n^2) \). Finally, we replace each pair at position \( p \) with a fresh letter based on the rank of \((\tilde{c}, \tilde{c})\). \( \blacksquare \)
4.1.2 BComp on CFGs

For any even \( h \) (\( 0 \leq h < \hat{h} \)), BComp can be implemented in a similar way to PComp of Lemma 16. A block \( T_h[b..e] \) of length \( \geq 2 \) is uniquely associated with a variable \( X \) that is the label of the lowest node covering the interval \([b - 1..e + 1]\) in the derivation tree of \( S_h \) (if \( b = 0 \) or \( e = |T_h| \), the block is associated with the starting variable). Here we take \([b - 1..e + 1]\) rather than \([b..e]\) to be sure that the block cannot extend outside the variable. Some blocks are explicitly written in \( D_h(X) \) and the others are crossing the boundaries of variables in \( D_h(X) \). The numbers of explicit blocks and crossing blocks in \( D_h \) is at most |\( S_h \)| and \( 2n \), respectively. The crossing blocks can be uncrossed in a similar way to uncrossing pairs. Then BComp can be done by replacing all the blocks with fresh letters on righthand sides of \( D_h \).

However here we have a problem. In order to give a unique letter to a block \( c^d \), we have to sort the pairs of integers \((c, d)\). Since \( d \) might be exponentially larger than |\( S_h \)| + \( n \), radix sort cannot be executed in \( O(|S_h| + n) \) time and space. In Section 6.2 of [10], Jeż showed how to solve this problem by tweaking the representation of lengths of long blocks, but its implementation and analysis are involved.⁶

We show in Lemma 17 our new observation, which leads to a simpler implementation and analysis of BComp. We say that a block \( c^d \) is short if \( d = O(|S_h| + n) \) and long otherwise. Also, we say that a variable is unary iff its righthand side consists of a single block.

▶ Lemma 17. For any even \( h \) (\( 0 \leq h < \hat{h} \)), a block \( T_h[b..e] = c^d \) is short if it does not include a substring generated from a unary variable.

Proof. Consider the derivation tree of \( S_h \) and the shortest path from \( T_h[b] \) to \( T_h[e] \). Let \( X_1X_2\cdots X_m \cdots X_m \) be the sequence of labels of internal nodes on the path, where \( X_m' \) corresponds to the lowest common ancestor of \( T_h[b] \) and \( T_h[e] \). Since SLPs have no loops in the derivation tree, \( X_1, \ldots, X_m \) are all distinct. Similarly \( X_{m+1}, \ldots, X_m \) are all distinct. Since a unary variable is not involved to generate the block, it is easy to see that \( d \leq \sum_{i=1}^{m}|D_h(X_i)| \leq 2|S_h| \) holds.

Lemma 17 implies that most of blocks we find during the compression are short, which can be sorted efficiently by radix sort. If there is a long block in \( D_h \), an occurrence of a unary variable \( X \) must be involved to generate the block. Since BComp at level \( h \) pops out all the letters from \( X \) and removes the occurrences of \( X \) in \( D_h \), there are at most 2\( n \) long blocks in total. The number of long blocks can also be upper bounded by \( 2N/n \) with a different analysis based on the following fact:

▶ Fact 18. If a substring of original text \( T \) generated from a long block overlaps with that generated from another long block, one substring must include the other, and moreover, the shorter block is completely included in “one” letter of the longer block. Hence the length of the substring of the longer block is at least \( n \) times longer than that of the shorter block.

Let us consider the long blocks that generate substrings whose lengths are \([n^i..n^{i+1}]\) for a fixed integer \( i \geq 1 \). By Fact 18, the substrings cannot overlap, and hence, the number of such long blocks is at most \( N/n^i \). Therefore, the total number of long blocks is at most \( \sum_{i \geq 1} N/n^i \leq 2N/n \). Thus we get the following lemma.

---

⁶ Note that Section 6.2 of [10] also takes care of the case where the word size is \( \Theta(\lg n) \) rather than \( \Theta(\lg N) \). We do not consider the \( \Theta(\lg n) \)-bits model in this paper because using \( \Theta(\lg N) \) bits to store the length of string generated by every letter is crucial for exact and LCE queries. However, we believe that our new observation stated in Lemma 17 will simplify the analysis for the \( \Theta(\lg n) \)-bits model, too.
18:12 Longest Common Extensions with Recompression

Lemma 19. There are at most $O(\min(n,N/n))$ long blocks found during SimTtoG.

By Lemma 19, we can employ a standard comparison-based sorting algorithm to sort all long blocks in $O(n \log \min(n,N/n))$ time in total. In particular, BComp of one level can be implemented in the following complexities:

Lemma 20. For any even $h$ ($0 \leq h < \hat{h}$), we can compute $S_{h+1}$ from $S_h$ in $O(|S_h| + n + m \log m)$ time and $O(|S_h| + n)$ space, where $m$ is the number of long blocks in $D_h$. In addition, $|S_{h+1}| \leq |S_h| + 2n$.

4.1.3 The complexities of SimTtoG

Theorem 21. SimTtoG runs in $O(n \log^2(N/n))$ time and $O(n \log(N/n))$ space.

Proof. Using PComp and BComp implemented on CFGs (see Lemma 16 and 20), SimTtoG transforms level by level $S_0$ into $S_1, S_2, \ldots, S_{\hat{h}}$. In each level, the size of CFGs can increase at most $2n$ by the procedure of uncrossing. Since $|S_h| = O(n \log N)$ for any $h$ ($0 \leq h < \hat{h}$), we get the time complexity $O(n \log^2 N)$ by simply applying Lemmas 16 and 20.

We can improve it to $O(n \log^2(N/n))$ by a similar trick used in the proof of Lemma 13. At some level $h'$ where $|T_{h'}|$ becomes less than $n$, we decompress $S_{h'}$ and switch to TtoG, which transforms $T_{h'}$ into $T_h$ in $O(n)$ time by Lemma 9. We apply Lemmas 16 and 20 only for $h$ with $0 \leq h < h'$. Since $h' = O(\log(N/n))$, $|S_h| = O(n \log(N/n))$ for any $h$ ($0 \leq h < h'$). Hence, we get the time complexity $O(n \log^2(N/n))$. The space complexity is bounded by the maximum size of CFGs $S_0, S_1, \ldots, S_{\hat{h}}$, which is $O(n \log(N/n))$.

4.2 GtoG: $O(n \log(N/n))$-time recompression

We modify SimTtoG slightly to run in $O(n \log(N/n))$ time and $O(n + z \log(N/z))$ space. The idea is the same as what has been presented in Section 6.1 of [10]. The problem of SimTtoG is that the sizes of intermediate CFGs $S_h$ can grow up to $O(n \log(N/n))$. If we can keep their sizes to $O(n)$, everything goes fine. This can be achieved by using two different types of partitions of $\Sigma_h$ for PComp: One is for compressing $T_h$ by a constant factor, and the other for compressing $|S_h|$ by a constant factor (unless $|S_h|$ is too small to compress). Recall that the former partition has been used in TtoG and SimTtoG, and the partition is computed from the adjacency list of $T_h$ by Algorithm 1. Algorithm 1 can be extended to work on a set of strings by just inputting the adjacency list from a set of strings. Then, we can compute the partition for compressing $|S_h|$ by a constant factor by considering the adjacency list from a set of strings in the righthand sides of $D_h$. The adjacency list can be easily computed in $O(|S_h| + n)$ time and space by modifying the algorithm described in the proof of Lemma 15: We just ignore the weight $\text{VOcc}(X)$, i.e., use a unit weight 1 for every listed pair. Using the two types of partitions alternately, we can compress strings by a constant factor while keeping the sizes of the intermediate CFGs to $O(n)$.

We denote the modified algorithm by GtoG and the resulting RLSLP by GtoG(S). Note that GtoG(S) is not identical to TtoG(T) in general because the partitions used in GtoG depend on the input $S$. Still the height of GtoG(S) is $O(\log N)$ and the properties of $PSeqs$ hold. Hence we can support LCE queries on GtoG(S) as we did on TtoG(T) by Lemma 14.

4.3 Proof of Theorem 2

Proof of Theorem 2. Let $S$ be an input SLP of size $n$ generating $T$. We compute GtoG(S) in $O(n \log(N/n))$ time and $O(n + z \log(N/z))$ space as described in Section 4.2. Since the
height of $\text{GtoG}(s)$ is $O(\lg N)$, we can support $\text{Extract}(i, \ell)$ queries in $O(\lg N + \ell)$ time due to Lemma 5. $\text{GtoG}(s)$ supports LCE queries in $O(\lg N)$ time in the same way as what was described in Lemma 14.

Appendix: Omitted proofs

A.1 Proof of Lemma 6

Proof. We first scan $w$ in $O(|w|)$ time and list all the blocks of length $\geq 2$. Each block $c^d$ ($c \in \Sigma, d \geq 2$) at position $i$ is listed by a triple $(c, d, i)$ of integers in $\Sigma$. Next we sort the list according to the pair of integers $(c, d)$, which can be done in $O(|w|)$ time and space by radix sort. Finally, we replace each block $c^d$ by a fresh letter based on the rank of $(c, d)$. $\blacktriangle$

A.2 Proof of Lemma 7

Proof. In the foreach loop, we first run a 1/2-approximation algorithm of maximum “undirected” cut problem on the adjacency list, i.e., we ignore the direction of the edges here. For each $c$ in increasing order, we greedily determine whether $c$ is added to $\hat{\Sigma}$ or to $\tilde{\Sigma}$ depending on $\sum_{\tilde{c} \in \hat{\Sigma}} \text{Freq}(c, \tilde{c}, \cdot) \geq \sum_{\tilde{c} \in \tilde{\Sigma}} \text{Freq}(c, \tilde{c}, \cdot)$. Note that $\sum_{\tilde{c} \in \hat{\Sigma}} \text{Freq}(c, \tilde{c}, \cdot)$ (resp. $\sum_{\tilde{c} \in \tilde{\Sigma}} \text{Freq}(c, \tilde{c}, \cdot)$) represents the number of edges between $c$ and a character in $\hat{\Sigma}$ (resp. $\tilde{\Sigma}$). By greedy choice, at least half of the edges in question become the ones connecting two characters each from $\hat{\Sigma}$ and $\tilde{\Sigma}$. Hence, in the end, $|E|$ becomes at least $(|w| - 1)/2$, where let $E$ denote the set...
of edges between characters from \( \hat{\Sigma} \) and \( \Sigma \) (recalling that there are exactly \(|w| - 1 \) edges). Since each edge in \( E \) corresponds to an occurrence of a pair from \( \hat{\Sigma} \Sigma \cup \Sigma \hat{\Sigma} \) in \( w \), at least one of the two partitions \((\hat{\Sigma}, \Sigma)\) and \((\Sigma, \hat{\Sigma})\) covers more than half of \( E \). Hence we achieve our final bound \(|E|/2 = (|w| - 1)/4 \) by choosing an appropriate partition at Line 7.

In order to see that Algorithm 1 runs in \( O(m) \) time, we only have to care about Line 3 and Line 7. We can compute \( \sum_{c \in \Sigma} \text{Freq}(c, \hat{c}, \cdot) \) and \( \sum_{c \in \Sigma} \text{Freq}(c, \cdot, \cdot) \) by going through all \( \text{Freq}(c, \cdot, \cdot) \) for fixed \( c \) in the adjacency list, which are consecutive in the sorted list. Since each element of the list is used only once, the cost for Line 3 is \( O(m) \) in total. Similarly the computation at Line 7 can be done by going through the adjacency list again. Thus the algorithm runs in \( O(m) \) time.

### A.3 Proof of Lemma 8

**Proof.** We first compute the adjacency list of \( w \). This can be easily done in \( O(|w|) \) time and space by sorting the \(|w| - 1 \) size multiset \( \{(w[i], w[i + 1], 0) \mid 1 \leq i < |w|, w[i] > w[i + 1]\} \cup \{(w[i + 1], w[i], 1) \mid 1 \leq i < |w|, w[i] < w[i + 1]\} \) by radix sort. Then by Lemma 7 we compute a partition \((\hat{\Sigma}, \Sigma)\) in linear time in the size of the adjacency list, which is \( O(|w|) \).

Next we scan \( w \) in \( O(|w|) \) time and list all the occurrences of pairs to be compressed. Each pair \( \hat{c} \in \hat{\Sigma} \Sigma \) at position \( i \) is listed by a triple \( (\hat{c}, \hat{c}, i) \) of integers in \( \Sigma \). Then we sort the list according to the pair of integers \((\hat{c}, \hat{c})\), which can be done in \( O(|w|) \) time and space by radix sort. Finally, we replace each pair with a fresh letter based on the rank of \((\hat{c}, \hat{c})\).

### A.4 Proof of Lemma 9

**Proof.** We first compute \( T_0 \) in \( O(N) \) by sorting the characters used in \( T \) and replacing them with ranks of characters. Then we compress \( T_0 \) by applying \( \text{BComp} \) and \( \text{PComp} \) by turns and get \( T_1, T_2 \ldots T_h \). One technical problem is that characters used in an input string \( w \) of \( \text{BComp} \) and \( \text{PComp} \) should be in \([1..|w|]\), which is crucial to conduct radix sort efficiently in \( O(|w|) \) time (see Lemmas 6 and 8). However letters in \( T_h \) do not necessarily hold this property. To overcome this problem, during computation we maintain ranks of letters among those used in the current \( T_h \), which should be in \([1..|T_h|]\), and use the ranks instead of letters for radix sort. If we have such ranks in each level, we can easily maintain them by radix sort for the next level. Now, in every level \( h \) \((0 \leq h < \hat{h})\) the compression from \( T_h \) to \( T_{h+1} \) can be conducted in \( O(|T_h|) \) time and space. Since \( \text{PComp} \) compresses a given string by a constant factor, the total running time can be bounded by \( O(N) \) time.

### A.5 Proof of Lemma 11

**Proof.** Since a block is compressed into one letter, the number of parent nodes of \( C \) is at most \( m \). As every internal node has two or more children, it is easy to see that there are \( O(m) \) ancestor nodes of the parent nodes of \( C \).
Abstract

Important papers have appeared recently on the problem of indexing binary strings for jumbled pattern matching, and further lowering the time bounds in terms of the input size would now be a breakthrough with broad implications. We can still make progress on the problem, however, by considering other natural parameters. Badkobeh et al. (IPL, 2013) and Amir et al. (TCS, 2016) gave algorithms that index a binary string in $O(n + \rho^2 \log \rho)$ time, where $n$ is the length and $\rho$ is the number of runs, and Giaquinta and Grabowski (IPL, 2013) gave one that runs in $O(n + \rho^2)$ time. In this paper we propose a new and very simple algorithm that also runs in $O(n + \rho^2)$ time and can be extended either so that the index returns the position of a match (if there is one), or so that the algorithm uses only $O(n)$ bits of space instead of $O(n)$ words.

1 Introduction

Since its introduction at the 2009 Prague Stringology Conference [6, 8], the problem of indexed binary jumbled pattern matching has been discussed in many top conferences and
journals. It asks us to preprocess a binary string such that later, given a number of 0s and a number of 1s, we can quickly report whether there exists a substring with those numbers of 0s and 1s and, optionally, return the position of one such substring or possibly even all of them. The naive preprocessing algorithm takes quadratic time but researchers have reduced that bound to $O(n^2/\log n)$ [5, 16], $O(n^2/\log^2 n)$ [17], $O(n^2/2^{O(\sqrt{\log n/\log \log n})})$ [4, 14] and finally $O(n^{1.869})$ with randomization or $O(n^{1.864})$ without [7].

Researchers have also looked at indexing for approximate matching [9, 10], indexed jumbled pattern matching over larger alphabets [2, 15], indexing labelled trees and other structures [9, 11, 12], and how to index faster when the (binary) input string is compressible. Gagie et al. [12] gave an algorithm that runs in $O(g^{2/3}n^{4/3})$ when the input is represented as a straight-line program with $g$ rules, and Badkobeh et al. [3] gave one that runs in $O(n + \rho^2 \log \rho)$ time when the input consists of $\rho$ runs, i.e., maximal unary substrings (we will denote later as $\rho$ the number of maximal substrings of 1s, for convenience). Giaquinta and Grabowski [13] gave two algorithms: one runs in $O(\rho^2 \log k + n/k)$ time, where $k$ is a parameter, and produces an index that uses $O(n/k)$ extra space and answers queries in $O(\log k)$ time; the other runs in $O(n^2 \log^2 (w)/w)$ time, where $w$ is the size of a machine word. Amir et al. [1] gave an algorithm that runs in $O(\rho^2 \log \rho)$ time when the input is a run-length encoded binary string, or $O(n + \rho^2 \log \rho)$ time when it is a plain binary string; it builds an index that takes $O(\rho^2)$ words and answers queries in $O(\log \rho)$ time, however. Very recently, Sugimoto et al. [19] considered the related problems of finding Abelian squares, Abelian periods and longest common Abelian factors, also on run-length encoded strings.

We first review some preliminary notions in Section 2. We present our main result in Section 3: a new and very simple indexing algorithm that runs in $O(n + \rho^2)$ time, which matches Giaquinta and Grabowski’s algorithm with the parameter $k = 1$ and is thus tied as the fastest known when $\rho = \Omega(n^{0.5}) \cap o(n^{0.932})$ and the smallest straight-line program for the input has $\omega(\rho^3/n^2)$ rules. For an input string of up to ten million bits, for example, if the average run-length is three or more then $\rho < n^{0.932}$. While Giaquinta and Grabowski found an efficient way to construct the Corner Index of Badkobeh et al. [3], our algorithm constructs a more direct index and takes only 17 lines of pseudocode, making it a promising starting point for investigating other possible algorithmic features. In Section 4, for example, we show how to extend our algorithm to store information that lets us report the position of a match (if there is one). Finally, in Section 5, we show how we can alternatively adapt it to use only $O(n)$ bits of space.

## Preliminaries

Consider a string $s \in \{0, 1\}^n$. We denote by $s[i \cdots j]$ the substring of $s$ consisting of the $i$th through $j$th characters, for $1 \leq i \leq j \leq n$; if $i = j$, we can also write simply $s[i]$. Cicalese et al. [6, 8] observed that, if we slide a window of length $k$ over $s$, the number of 1s in the window can change by at most 1 at each step. It follows that if $s[i \cdots i + k - 1]$ contains $x$ copies of 1 and $s[j \cdots j + k - 1]$ contains $z$ copies of 1 with $i \leq j$ then, for $y$ between $x$ and $z$ (notice $x$ could be smaller than, larger than, or equal to $z$), there is a substring of length $k$ in $s[i \cdots j + k - 1]$ with exactly $y$ copies of 1. This immediately implies the following theorem:

### Theorem 1

Let $x$ and $z$ be the minimum and maximum numbers of 1s in any substring of length $k$. There is a substring of length $k$ with $y$ copies of 1 if and only if $x \leq y \leq z$.

By Theorem 1, if we compute and store, for $1 \leq k \leq n$, the minimum and maximum numbers of 1s in a substring of $s$ of length $k$ then later, given a number of 0s and a number
of 1s, we can report in constant time whether there exists a substring with that many 0s and 1s. For example, if \( s = 010101110011 \) then, as \( k \) goes from 1 to \( n = 12 \), the minimum and maximum numbers of 1s are 0, 0, 1, 2, 2, 3, 4, 4, 5, 6, 7 and 1, 2, 3, 3, 4, 4, 5, 5, 6, 6, 7, respectively. Since the fifth numbers in these lists are 2 and 4, we know that there are substrings of length 5 with exactly 2, 3 and 4 copies of 1, but none with 0, 1 or 5 (or more than 5, obviously).

Cicalese et al. [9] noted that, if we also store the positions of the substrings with the minimum and maximum numbers of 1s and a bitvector for \( s \) that supports constant time rank queries, then via binary search in \( O(\log n) \) time we can find an example of a substring with any desired numbers of 0s and 1s, called a witness if such a substring exists. (The query \( \text{rank}(i) \) returns the number of 1s in \( s[1 \cdots i] \); see, e.g., [18] for more details of rank queries on bitvectors.) For example, suppose we want to find a substring of length 5 with exactly 3 copies of 1 in our example string \( s \). We have stored that there are substrings of length 5 with 2 and 4 copies of 1 starting at positions 1 and 4, respectively, so we know there is a substring of length 5 with exactly 3 copies of 1 starting in \( s[1 \cdots 4] \). We choose \( \lfloor (1 + 4)/2 \rfloor = 2 \) and check how many 1s there are in \( s[2 \cdots 2 + 5 - 1 = 6] \) via two rank queries. In this case, the answer is 3, so we have found a witness in one step; otherwise, we would know there is a witness starting in \( s[3 \cdots 4] \) and we would recurse on that interval.

The same authors noted that in each step, the lists of minimum and maximum numbers can only stay the same or increment, so we can represent each list as a bitvector of length \( n \) and support access to it using rank queries. For example, the bitvector for the list of minimum numbers in our example is 001101101011, so rank(i) returns the \( i \)th number in the list. Since an \( n \)-bit bitvector takes \( O(n) \) bits of space, it follows that we can store our index in \( O(n) \) bits and still support constant-time queries, if we do not want a witness. We note, however, that even though the input \( s \) takes \( n \) bits and the resulting index takes \( O(n) \) bits, all previous constructions have used \( \Omega(n) \) words of workspace in the worst case.

A run in \( s \) is a maximal unary substring and the run-length encoding \( \text{rle}(s) \) is obtained by replacing each run by a copy of the character it contains and its length. Although \( \rho \) is usually used to denote the number of runs, for convenience, we use it to denote only the number of runs of 1s – about half its normal value for binary strings – and consider \( s \) to begin and end with (possibly empty) runs of 0s. For example, for our example string the run-length encoding is 0\(^1\)1\(^1\)0\(^1\)1\(^1\)0\(^1\)1\(^0\)2\(^1\)0\(^0\) and \( \rho = 4 \) (instead of 9). We denote the lengths of the runs of 0s and 1s as \( z[0], \ldots, z[\rho] \) and \( o[1], \ldots, o[\rho] \), respectively.

### 3 Basic Indexing

Since finding substrings with the minimum numbers of 1s is symmetric to finding substrings with the maximum numbers of 1s (e.g., by taking the complement of the string), we describe how, given a binary run-length encoded string \( s[1 \cdots n] \), we can build a table \( T[1 \cdots n] \) such that \( T[k] = f(k) \), where \( f(k) \) denotes the maximum number of 1s in a substring of \( s \) of length \( k \).

The complete pseudo-code of our algorithm – only 17 lines – is shown as Algorithm 1. The starting point of our explanation and proof of correctness is the observation that, if the bit immediately to the left of a substring is a 1, we can shift the substring one bit left without decreasing the number of 1s; if the first bit of the substring is a 0, then we can shift the substring one bit right (shortening it on the right if necessary) without decreasing the number of 1s. It follows that, for \( 1 \leq k \leq n \), there is a substring of length at most \( k \) containing \( f(k) \) copies of 1 and starting at the beginning of a run of 1s. Since we can remove
any trailing 0s from such a substring also without changing the number of 1s, there is such a substring that also ends in a run of 1s. Therefore we have the following lemma:

**Lemma 2.** For $1 \leq k \leq n$, there is a substring of length at most $k$ containing $f(k)$ copies of 1, starting at the beginning of a run of 1s and ending in a run of 1s.

Applying Lemma 2 immediately yields an $O(n)\rho$-time algorithm: set $T[1 \cdot \cdot n]$ to all 0s; for each position $i$ at the beginning of a run of 1s and each position $j \geq i$ in a run of 1s, set $T[j - i + 1] = \max(T[j - i + 1], s[i] + \cdots + s[j])$; finally, because $f$ is non-decreasing, make a pass over $T$ from $T[2]$ to $T[n]$ setting each $T[i] = \max(T[i], T[i - 1])$. Computing the number $s[i] + \cdots + s[j]$ of 1s in a substring $s[i \cdot \cdot j]$ starting at the beginning of a run of 1s and ending in a run of 1s is easy to do from the run-length encoding in amortized constant time.

To speed this preliminary algorithm up to run in $O(n + \rho^2)$ time, we first observe that, if $\ell$ is the length of a substring starting at the beginning of a run of 1s, ending in a run of 1s and containing $f(\ell)$ copies of 1, and $d > \ell$ is the length of a substring starting at the beginning of a run of 1s and ending at the end of a run of 1s, then $f(\ell) \geq f(d) - d + \ell$. (In fact this is true for any $\ell$ and $d \geq \ell$, simply because $f(x + 1) \leq f(x) + 1$ for all $x$.) We then observe that, for some such $d$, we have $f(\ell) = f(d) - d + \ell$. To see why, consider any substring $s[i \cdot \cdot j]$ of length $\ell$ starting at the beginning of a run of 1s, ending within a run of 1s and containing $f(\ell)$ copies of 1: let $d$ be the length of the substring starting at $s[i]$ and ending at the end of the run of 1s containing $s[i + \ell - 1]$, so $f(\ell) = f(d) - d + \ell$.

**Lemma 3.** If $\ell$ is the length of a substring starting at the beginning of a run of 1s, ending in a run of 1s and containing $f(\ell)$ copies of 1, and $d > \ell$ is the length of a substring starting at the beginning of a run of 1s and ending at the end of a run of 1s, then $f(\ell) \geq f(d) - d + \ell$. Furthermore, for some such $d$, we have $f(\ell) = f(d) - d + \ell$.

With Lemma 3, we can compute the number $s[i] + \cdots + s[j]$ of 1s in each substring $s[i \cdot \cdot j]$ starting at the beginning of a run of 1s and ending in a run of 1s, in a total of $O(n + \rho^2)$ time:

---

Algorithm 1: Building the index table $T$ of string $s$.

```plaintext
for $i = 1, \ldots, n$ do
  $T[i] = 0$
for $i = 1, \ldots, \rho$ do
  ones = $o[i]$
  zeros = 0
  $T[ones] = ones$
for $j = i + 1, \ldots, \rho$ do
  ones += $o[j]$
  zeros += $z[j - 1]$
  if ones $> T[ones + zeros]$ then
    $T[ones + zeros] = ones$
for $i = n - 1, \ldots, 1$ do
  if $T[i] < T[i + 1] - 1$ then
    $T[i] = T[i + 1] - 1$
for $i = 2, \ldots, n$ do
  if $T[i] < T[i - 1]$ then
    $T[i] = T[i - 1]$
```
again, set $T[1 \cdots n]$ to all 0s; for each position $i$ at the beginning of a run of 1s and each position $j \geq i$ at the end of a run of 1s, set $T[j - i + 1] = \max(T[j - i + 1], s[i] + \cdots + s[j])$; make a pass over $T$ from $T[n - 1]$ to $T[1]$ setting each $T[i] = \max(T[i], T[i + 1] - 1)$. Computing the number $s[i] + \cdots + s[j]$ of 1s in a substring $s[i \cdots j]$ starting at the beginning of a run of 1s and ending at the end of a run of 1s is again easy to do from the run-length encoding in amortized constant time.

Combining Lemmas 2 and 3, we have a complete algorithm for computing $T$ in $O(n + \rho^2)$ time: set $T[1 \cdots n]$ to all 0s; for each position $i$ at the beginning of a run of 1s and each position $j \geq i$ at the end of a run of 1s, set $T[j - i + 1] = \max(T[j - i + 1], s[i] + \cdots + s[j])$; make a pass over $T$ from $T[n - 1]$ to $T[1]$ setting each $T[i] = \max(T[i], T[i + 1] - 1)$ (which sets $T[\ell]$ correctly for every length $\ell$ of a substring starting at the beginning of a run of 1s, ending in a run of 1s and containing $f(\ell)$ copies of 1); and make a pass over $T$ from $T[2]$ to $T[n]$ setting each $T[i] = \max(T[i], T[i - 1])$ (which sets every entry in $T$ correctly). Once we have $T$, we can convert it into a bitvector in $O(n)$ time. Summarizing our results so far, we have the following theorem, which we adapt in later sections:

**Theorem 4.** Given a binary string $s$ of length $n$ containing $\rho$ runs of 1s, we can build an $O(n)$-bit index for constant-time jumbled pattern matching in $O(n + \rho^2)$ time.

Now we examine how our algorithm works on our example $s = 010101110011$. First we set all entries of $T$ to 0, then we loop through the runs of 1s and, for each, loop through the runs of 1s not earlier, computing distance from the start of the first to the end of the second and the number of 1s between those positions. While doing this, we set $T[1] = 1$, the number of 1s from the start to the end of the first run of 1s; $T[3] = 2$, the number of 1s from the start of the first run of 1s to the end of the second run of 1s; $T[7] = 5$, the number of 1s from the start of the first run of 1s to the end of the third run of 1s; $T[11] = 7$, the number of 1s from the start of the first run of 1s to the end of the fourth run of 1s; $T[5] = 4$, the number of 1s from the start of the second run of 1s to the end of the third run; etc. When we have finished this stage, $T = [1, 2, 3, 0, 4, 0, 5, 0, 6, 0, 7, 0]$. We then make a pass over $T$ from right to left, setting each $T[i] = \max(T[i], T[i + 1] - 1)$. After this stage, $T = [1, 2, 3, 3, 4, 4, 5, 5, 6, 6, 7, 0]$. Finally, we make a pass over $T$ from left to right, setting each $T[i] = \max(T[i], T[i - 1])$. This fills in $T[12]$ and leaves $T$ correctly computed as $T = [1, 2, 3, 3, 4, 4, 5, 5, 6, 6, 7, 7]$.

## 4 Witnessing Index

As described in Section 2, if together with computing the minimum and maximum number of 1s in a substring of length $k$ for $1 \leq k \leq n$, we also store the positions of substrings of length $k$ with those numbers of 1s, and a single bitvector for $s$, then, together with confirming that $s$ contains a substring with a given number of 0s and 1s (if it does), we can give the starting position of such a substring, still in constant time.

In this section, we show how to modify our algorithm from Section 3 to build also a table $P[1..n]$ such that $P[k]$ is the starting position of a substring of length $k$ containing $f(k)$ copies of 1s. Computing and storing the starting position of a substring of length $k$ with the minimum number of 1s is symmetric.

First, notice that during the first stage of Algorithm 1, whenever we set $T[k] = f(k)$, we have found a substring of length $k$ containing $f(k)$ copies of 1, so we can set $P[k]$ at the same time. Now consider the second stage of the algorithm, in which we make a right-to-left pass over $T$ setting $T[i] = \max(T[i], T[i + 1] - 1)$ for $1 \leq i \leq n - 1$. When we start this stage, for every positive entry in $T$ we have set the corresponding entry in $P$. Therefore, by
induction, whenever we set $T[i] = T[i + 1] - 1$, we have $P[i + 1]$ set to the starting position of a substring of length $i + 1$ containing $T[i + 1]$ copies of 1. The substring of length $i$ starting at $P[i + 1]$ contains at least $T[i + 1] - 1$ copies of 1, so we can set $P[i] = P[i + 1]$. In the last stage of the algorithm, in which we make a left-to-right pass over $T$, we can almost use the same kind of argument and simply copy $P$ values when we copy $T$ values, except that we must ensure the starting positions we copy are far enough to the left of the end of the string (i.e., that the substrings have the correct lengths). Our modified algorithm is shown as Algorithm 2—still only 25 lines—and we now have the following theorem:

- **Theorem 5.** Given a binary string $s$ of length $n$ containing $\rho$ runs of 1s, we can build an $O(n)$-word index for constant-time jumbled pattern matching with $O(\log n)$ time witnessing in $O(n + \rho^2)$ time.

Running our modified algorithm on our example $s = 010101110011$, in the first stage we set $T = [1, 2, 3, 0, 4, 0, 5, 0, 6, 0, 7, 0]$ and, simultaneously, $P = [2, 11, 6, 0, 4, 0, 2, 0, 4, 0, 2, 0]$, where 0 indicates an unset value in $P$. In the second stage, we set $T = [1, 2, 3, 4, 4, 5, 6, 7, 0]$ and $P = [2, 11, 6, 4, 4, 2, 2, 4, 2, 2, 0]$. Finally, in the third stage, we fill in $T[12] = T[11]$, but we cannot just set $P[12] = P[11] = 2$ because $s[2\cdots n = 12]$ has length only 11, so we set $P[12] = 1$.

5 Reducing Workspace

It is frustrating that both $s$ and the index described in Theorem 4 take $O(n)$ bits to build the index. In this section, we show how to reduce this workspace to $O(n)$ bits also, without increasing the time bound for construction by more than a constant factor.

Suppose we divide $T$ into blocks of size $\lg(n)/2$ and modify our algorithm such that, whenever we set a value $T[j]$ in the same block with $j < i$ is at least $T[i] - i + j$ and each value $T[j]$ in the same block with $i < j$ is at least $T[i]$. Since we would eventually set each such $T[j]$ to a value at least as great during the normal execution of the algorithm, this does not change its correctness, apart from perhaps slowing it down by an $O(\log n)$ factor.

For any two consecutive values $T[i]$ and $T[i + 1]$ in the same block now, however, we have $T[i] \leq T[i + 1] \leq T[i] + 1$. We can thus store each block by storing its first value and a binary string of length $\lg(n)/2$ whose bits indicate where the values in the block increase. Therefore, we need a total of only $O(n)$ bits to store all the blocks.

Notice that, if we increase a value $T[i]$ by more than $\lg(n)/2$, we reset the first value $T[h]$ of the block to be $T[i] - i + h$, set the leading bits of the block to 1s to indicate that the values increase until reaching $T[i]$, and set the later bits of the block to 0s to indicate that the values remain equal to $T[i]$ until the end of the block. Therefore, we can speed the algorithm up to run in $O(n + \rho^2)$ time again, by using a universal table of size $2^{\lg(n)/2 \log^{O(1)} n} = o(n^{1/2 + \epsilon})$ to decide how to update blocks when we set values in them.

- **Theorem 6.** Given a binary string $s$ of length $n$ containing $\rho$ runs of 1s, we can build an $O(n)$-bit index for constant-time jumbled pattern matching in $O(n + \rho^2)$ time using $O(n)$ bits of workspace.

In fact, it seems possible to make the algorithm run in $O(n + \rho^2)$ time and $O(n)$ bits of space even without a universal table, using AC0 operations on words that are available on standard architectures.
Algorithm 2: Building the tables $T$ and $P$ for $s$.

1. for $i = 1, \ldots, n$ do
2.     $T[i] = 0$
3.     $p = z[0]$
4. for $i = 1, \ldots, \rho$ do
5.     $\text{ones} = o[i]$
6.     $\text{zeros} = 0$
7.     $T[\text{ones}] = \text{ones}$
8.     $P[\text{ones}] = p$
9. for $j = i + 1, \ldots, \rho$ do
10.     $\text{ones} += o[j]$
11.     $\text{zeros} += z[j - 1]$
12.     if $\text{ones} > T[\text{ones} + \text{zeros}]$ then
13.         $T[\text{ones} + \text{zeros}] = \text{ones}$
14.         $P[\text{ones} + \text{zeros}] = p$
15.     $p += \text{ones}[i] + \text{zeros}[i]$
16. for $i = n - 1, \ldots, 1$ do
17.     if $T[i] < T[i + 1] - 1$ then
18.         $T[i] = T[i + 1] - 1$
19.         $P[i] = P[i + 1]$
20. for $i = 2, \ldots, n$ do
21.     if $T[i] < T[i - 1]$ then
22.         $T[i] = T[i - 1]$
23.         $P[i] = P[i - 1]$
24.     if $P[i] + i > n$ then
25.         $P[i] = n - i$

This workspace reduction makes little sense for a string as small as our example $s = 010101110011$ but, for the sake of argument, suppose we partition our array $T$ for it into three blocks of length 4 each. We keep $T[1], T[5]$ and $T[9]$ stored explicitly and represent the other entries of $T$ implicitly with three 3-bit binary strings $B_1, B_2$ and $B_3$. Initially we set $T[1] = T[5] = T[9] = 0$ and $B_1 = B_2 = B_3 = 000$. Recall from Section 3 that we first set $T[1] = 1$, the number of 1s from the start to the end of the first run of 1s. At this point, we do not need to change $B_1$. We then set $T[3] = 2$ – the number of 1s from the start of the first run of 1s to the end of the second run of 1s – by setting $B_1 = 010$: starting from $T[1] = 1$, this encodes $T[2] = T[1] + 0 = 1$, $T[3] = T[1] + 0 + 1 = 2$ and $T[4] = T[1] + 0 + 1 + 0 = 2$. Next we set $T[7] = 5$ – the number of 1s from the start of the first run of 1s to the end of the third run of 1s – by setting $T[5] = 3$ and $B_2 = 110$: starting from $T[5] = 3$, this encodes $T[6] = T[5] + 1 = 4$, $T[7] = T[5] + 1 + 1 = 5$ and $T[8] = T[5] + 1 + 1 + 0 = 5$. Continuing like this, we set $T[11] = 7$ by setting $T[9] = 5$ and $B_3 = 110$; set $T[5] = 4$ and $B_2 = 010$: etc. When we are finished this stage, $T[1] = 1, T[5] = 4$ and $T[9] = 6$, and $B_1 = 110, B_2 = 010$ and $B_3 = 010$, encoding $T = [1, 2, 3, 3, 4, 4, 5, 5, 6, 6, 7, 7]$. In this case the final right-to-left and left-to-right passes have no effect, but there are cases (e.g., when we do not set any values in a certain block) when they are still necessary.

Abstract
The constrained LCS problem asks one to find a longest common subsequence of two input strings $A$ and $B$ with some constraints. The STR-IC-LCS problem is a variant of the constrained LCS problem, where the solution must include a given constraint string $C$ as a substring. Given two strings $A$ and $B$ of respective lengths $M$ and $N$, and a constraint string $C$ of length at most $\min\{M, N\}$, the best known algorithm for the STR-IC-LCS problem, proposed by Deorowicz (Inf. Process. Lett., 11:423–426, 2012), runs in $O(MN)$ time. In this work, we present an $O(mN + nM)$-time solution to the STR-IC-LCS problem, where $m$ and $n$ denote the sizes of the run-length encodings of $A$ and $B$, respectively. Since $m \leq M$ and $n \leq N$ always hold, our algorithm is always as fast as Deorowicz’s algorithm, and is faster when input strings are compressible via RLE.

1 Introduction

Longest common subsequence (LCS) is one of the most basic measures of similarity between strings, and there is a vast amount of literature concerning its efficient computation. An LCS of two strings $A$ and $B$ of lengths $M$ and $N$, respectively, is a longest string that is a subsequence of both $A$ and $B$. There is a well known $O(MN)$ time and space dynamic programming (DP) algorithm [15] to compute an LCS between two strings. LCS has applications in bioinformatics [10, 16], file comparisons [9, 8], pattern recognition [13], etc.

Recently, several variants of the problem which try to find a longest common subsequence that satisfy some constraints have been considered. In 2003, Tsai [14] proposed the constrained LCS (CLCS) problem, where, given strings $A, B$ with respective lengths $M, N$, and a constraint string $C$ of length $K$, the problem is to find a longest string that contains $C$ as a subsequence and is also a common subsequence of $A$ and $B$. Tsai gave an $O(M^2N^2K)$ time

solution, which was improved in 2004 by Chin et al. to $O(MNK)$ time [6]. Variants of the constrained LCS problem called SEQ-IC-LCS, SEQ-EC-LCS, STR-IC-LCS, and STR-EC-LCS, were considered by Chen and Chao in 2011 [5]. Each problem considers as input, three strings $A, B$ and $C$, and the problem is to find a longest string that includes (IC) or excludes (EC) $C$ as a subsequence (SEQ) or substring (STR) and is a common subsequence of $A$ and $B$ (i.e., CLCS is equivalent to the SEQ-IC-LCS problem). The best solution for each of the problems is shown in Table 1.

In order to speed up the LCS computation, one direction of research that has received much attention is to apply compression, namely, run-length encoding (RLE) of strings. Bunke and Csirik [4] were one of the first to consider such a scenario, and proposed an $O(mN + nM)$ time algorithm. Here, $m, n$ are the sizes of the RLE of the input strings of lengths $M$ and $N$, respectively. Notice that since RLE can be computed in linear time, and $m \leq M$ and $n \leq N$, the algorithm is always asymptotically faster than the standard $O(NM)$ time dynamic programming algorithm, especially when the strings are compressible by RLE. Furthermore, Ahsan et al. proposed an algorithm which runs in $O((m + n) + R\log\log(mn) + R\log\log(M + N))$ time [1], where $R$ is the total number of pairs of runs of the same character in the two RLE strings, i.e. $R \in O(mn)$, and the algorithm can be much faster when the strings are compressible by RLE.

For the constrained LCS problems, RLE based solutions for only the SEQ-IC-LCS problem have been proposed. In 2012, an $O(K(mN + nM))$ time algorithm was proposed by Ann et al. [2]. Later, in 2015, Liu et al. proposed a faster $O(M + N + K \min\{mN, nM\})$ time algorithm [12].

In this paper, we present the first RLE based solution for the STR-IC-LCS problem that runs in $O(mN + nM)$ time. Again, since RLE can be computed in linear time, and $m \leq M$ and $n \leq N$, the proposed algorithm is always asymptotically faster than the best known solution for the STR-IC-LCS problem by Deorowicz [7], which runs in $O(MN)$ time.

A common criticism against RLE based solutions is a claim that, although they are theoretically interesting, since most strings “in the real world” are not compressible by RLE, their applicability is limited and they are only useful in extreme artificial cases. We believe that this is not entirely true. There can be cases where RLE is a natural encoding of the data, for example, in music, a melody can be expressed as a string of pitches and their duration. Furthermore, in the data mining community, there exist popular preprocessing schemes for analyzing various types of time series data, which convert the time series to strings over a fairly small alphabet as an approximation of the original data, after which various analyses are conducted (e.g. SAX (Symbolic Aggregate approXimation) [11], clipped bit representation [3], etc.). These conversions are likely to produce strings which are compressible by RLE (and in fact, shown to be effective in [3]), indicating that RLE based solutions may have a wider range of application than commonly perceived.

2 Preliminaries

Let $\Sigma$ be the finite set of characters, and $\Sigma^*$ be the set of strings. For any string $A$, let $|A|$ be the length of $A$. For any $1 \leq i \leq |A|$, let $A[i]$ be the $i$th character of $A$ and let $A[i..i'] = A[i] \cdots A[i']$ denote a substring of $A$. Especially, $A[1..i]$ denotes a prefix of $A$, and $A[i..|A|]$ denotes a suffix of $A$. A string $Z$ is a subsequence of $A$ if $Z$ can be obtained from $A$ by removing zero or more characters. For two string $A$ and $B$, a string $Z$ is a longest common subsequence (LCS) of $A,B$, if $Z$ is a longest string that is a subsequence of both $A$ and $B$. For any $1 \leq i \leq |A|$ and $1 \leq j \leq |B|$, let $L^{\text{pref}}(i,j)$ denote the length of an LCS of $A[1..i], B[1..j]$, and let $L^{\text{suf}}(i,j)$ denote the length of an LCS of $A[i..|A|], B[j..|B|]$. The LCS problem is to compute the length of an LCS of given two strings $A$ and $B$. A well known solution is dynamic programming, which computes in $O(MN)$ time, a table (which we will call DP table) of size $O(MN)$ that stores values of $L^{\text{pref}}(i,j)$ for all $1 \leq i \leq M$, $1 \leq j \leq N$. The DP table for $L^{\text{suf}}(i,j)$ can be computed similarly.

For two strings $A,B$ and a constraint string $C$, a string $Z$ is an STR-IC-LCS of $A,B,C$, if $Z$ is a longest string that includes $C$ as a substring and is also a subsequence of both $A$ and $B$. The STR-IC-LCS problem is to compute the length of an STR-IC-LCS of any given three strings $A,B$ and $C$. For example, if $A = \text{abacab}, B = \text{babcaba}, C = \text{bb}$, then $\text{abacab}$ and $\text{babcaba}$ are LCSs of $A, B$ and $\text{abcab}$ is an STR-IC-LCS of $A, B, C$.

The run-length encoding (RLE) of a string $A$ is a kind of compressed representation of $A$ where each maximal run of the same character is represented by a pair of the character and the length of the run. Let $\text{RLE}(A)$ denote the RLE of a string $A$. The size of $\text{RLE}(A)$ is the number of the runs in $A$, and is denoted by $|\text{RLE}(A)|$. By definition, $|\text{RLE}(A)|$ is always less than or equal to $|A|$.

In the next section, we consider the STR-IC-LCS problem of strings $A,B$ and constraint string $C$. Let $|A| = M$, $|B| = N$, $|C| = K$, $|\text{RLE}(A)| = m$ and $|\text{RLE}(B)| = n$. We assume that $K \leq \min(M,N)$ and $|\text{RLE}(C)| \leq \min(m,n)$, since otherwise there is no solution. We also assume that $K > 0$, because in that case the problem becomes the normal LCS problem of $A,B$.

3 Algorithm

In this section, we will first introduce a slightly modified version of Deorowizc’s $O(MN)$-time algorithm for the STR-IC-LCS problem [7], and then propose our $O(mN + nM)$-time algorithm, which is based on his dynamic programming approach, but uses RLE.

3.1 Deorowizc’s $O(MN)$ Algorithm

We first define the notion of minimal $C$-intervals of a string.

\begin{itemize}
    \item **Definition 1.** For any strings $A$ and $C$, an interval $[s,f]$ is a minimal $C$-interval of $A$ if
        \begin{itemize}
            \item $C$ is a subsequence of $A[s..f]$, and
            \item $C$ is not a subsequence of $A[s+1..f]$ or $A[s..f-1]$.
        \end{itemize}
\end{itemize}

Deorowizc’s algorithm is based on Lemma 2, which is used implicitly in [7].

\begin{itemize}
    \item **Lemma 2 (implicit in [7]).** If $Z$ is an STR-IC-LCS of $A,B,C$, then there exist minimal $C$-intervals $[s,f],[s',f']$ ($1 \leq s \leq f \leq M$, $1 \leq s' \leq f' \leq N$) respectively of $A$ and $B$, such that $Z = XCY$, where $X$ is an LCS of $A[1..s-1]$ and $B[1..s'-1]$ and $Y$ is an LCS of $A[f+1..M]$ and $B[f'+1..N]$.
\end{itemize}
Proof. From the definition of STR-IC-LCS, C is a substring of Z, and therefore, there exist (possibly empty) strings X, Y such that \( Z = XCY \). Also, since Z is a common subsequence of A and B, there exist monotonically increasing sequences \( i_1, \ldots, i_{|Z|} \) and \( j_1, \ldots, j_{|Z|} \) such that \( Z = A[i_1] \cdots A[i_{|Z|}] = B[j_1] \cdots B[j_{|Z|}] \), and \( C = A[i_{|X|}+1] \cdots A[i_{|X|+|K|}] = B[j_{|X|+1}+1] \cdots B[j_{|X|+|K|}] \).

Now, since \( C \) is a subsequence of \( A[i_{|X|}+1..i_{|X|+|K|}] \) and \( B[j_{|X|+1}..j_{|X|+|K|}] \) there exist minimal \( C \)-intervals \([s, f]\) respectively of A and B that satisfy \( i_{|X|+1} \leq s \leq f \leq i_{|X|+|K|} \), and \( j_{|X|+1} \leq s' \leq f' \leq j_{|X|+|K|} \). Let \( X' \) be an LCS of \( A[1..s-1] \) and \( B[1..s'-1] \), and \( Y' \) an LCS of \( A[f+1..M] \) and \( B[f'+1..N] \). Since X must be a common subsequence of \( A[1..s-1] \) and \( B[1..s'-1] \), and Y a common subsequence of \( A[f+1..M] \) and \( B[f'+1..N] \), we have \( |X'| \geq |X| \) and \( |Y'| \geq |Y| \). However, we cannot have that \( |X'| > |X| \) or \( |Y'| > |Y| \) since otherwise, \( X'CY' \) would be a string longer than Z that contains C as a substring, and is a common subsequence of A, B, contradicting that Z is an STR-IC-LCS of A, B, C. Thus, \( |X| = |X'| \) and \( |Y| = |Y'| \) implying that X is also an LCS of \( A[1..s-1], B[1..s'-1] \), and Y is also an LCS of \( A[f+1..M], B[f'+1..N] \), proving the lemma. ▷

The algorithm consists of the following two steps, whose correctness follows from Lemma 2.

**Step 1.** Compute all minimal \( C \)-intervals of A and B.

**Step 2.** For all pairs of a minimal \( C \)-interval \([s, f]\) of A and a minimal \( C \)-interval \([s', f']\) of B, compute the length of an LCS of the corresponding prefixes of A and B (i.e., \( L^{\text{pref}}(s-1, s'-1) \)) and that of the corresponding suffixes of A and B (i.e., \( L^{\text{suf}}(f+1, f'+1) \)). The largest sum of LCS lengths plus \( |C| \) (i.e., \( L^{\text{pref}}(s-1, s'-1) + L^{\text{suf}}(f+1, f'+1) + |C| \)) is the length of an STR-IC-LCS.

The steps can be executed in the following running times. For Step 1, there are respectively at most \( M + N \) minimal \( C \)-intervals of A and B, which can be enumerated in \( O(MN) \) time. For Step 2, we precompute, in \( O(MN) \) time, two dynamic programming tables which respectively contain the values of \( L^{\text{pref}}(i, j) \) and \( L^{\text{suf}}(i, j) \) for each \( 1 \leq i \leq M \) and \( 1 \leq j \leq N \). Using these tables, the value \( L^{\text{pref}}(s-1, s'-1) + L^{\text{suf}}(f+1, f'+1) + |C| \) can be computed in constant time for any \([s, f]\) and \([s', f']\). There are \( O(MN) \) possible pairs of minimal \( C \)-intervals, so Step 2 can be done in \( O(MN) \) time. In total, since \( K \leq M, K \leq N \), the STR-IC-LCS problem can be solved in \( O(MN) \) time.

We note that in the original presentation of Deorowicz’s algorithm, right-minimal \( C \)-intervals, that is, intervals \([s, f]\) where C is a subsequence of \( A[s..f] \) but not of \( A[s..f-1] \) are computed, instead of minimal \( C \)-intervals as defined in Definition 1. Although the number of considered intervals changes, this does not influence the asymptotic complexities in the non-RLE case. However, as we will see in Lemma 4 of Section 3.2, this is an essential difference for the RLE case, since, when \( |RLE(C)| = 1 \), the number of minimal \( C \)-intervals of A and B can be bounded by \( O(m) \) and \( O(n) \), but the number of right-minimal \( C \)-intervals of A and B cannot, and are only bounded by \( O(M) \) and \( O(N) \).

### 3.2 Our Algorithm via RLE

In this subsection, we propose an efficient algorithm based on Deorowicz’s algorithm explained in Subsection 3.1, extended to strings expressed in RLE. There are two main cases to consider: when \( |RLE(C)| = 1 \), i.e., when C consists of only one type of character, and when \( |RLE(C)| > 1 \), i.e., when C contains at least two different characters.
3.2.1 Case $|\text{RLE}(C)| > 1$

\[ \text{Theorem 3.} \text{ Let } A, B, C \text{ be any strings and let } |A| = M, |B| = N, |\text{RLE}(A)| = m \text{ and } |\text{RLE}(B)| = n. \text{ If } |\text{RLE}(C)| > 1, \text{ we can compute the length of an STR-IC-LCS of } A, B, C \text{ in } O(mN + nM) \text{ time.} \]

For Step 1, we execute the following procedure to enumerate all minimal $C$-intervals of $A$ and $B$. Let $s_0 = 0$. First, find the right minimal $C$-interval starting at $s_0 + 1$, i.e., the smallest position $f_1$ such that $C$ is a subsequence of $A[s_0 + 1..f_1]$. Next, starting from position $f_1$ of $A$, search backwards to find the left minimal $C$-interval ending at $f_1$, i.e., the largest position $s_1$ such that $C$ is a subsequence of $A[s_1..f_1]$. The process is then repeated, i.e., find the smallest position $f_2$ such that $C$ is a subsequence of $A[s_1 + 1..f_2]$, and then search backwards to find the largest position $s_2$ such that $C$ is a subsequence of $A[s_2..f_2]$, and so on. It is easy to see that the intervals $[s_1, f_1], [s_2, f_2], \ldots$ obtained by repeating this procedure until reaching the end of $A$ are all the minimal $C$-intervals of $A$, since each interval that is found is distinct, and there cannot exist another minimal $C$-interval between those found by the procedure. The same is done for $B$. For non-RLE strings, this takes $O((M + N)K)$ time.

The lemma below shows that the procedure can be implemented more efficiently using RLE.

\[ \text{Lemma 4.} \text{ Let } A \text{ and } C \text{ be strings where } |A| = M, |\text{RLE}(A)| = m \text{ and } |C| = K. \text{ If } |\text{RLE}(C)| > 1, \text{ the number of minimal } C \text{-intervals of } A \text{ is } O(m) \text{ and can be enumerated in } O(M + nK) \text{ time.} \]

\[ \text{Proof.} \text{ Because } |\text{RLE}(C)| > 1, \text{ it is easy to see from the backward search in the procedure described above, that for any minimal } C \text{-interval of } A, \text{ there is a unique run of } A \text{ such that the last character of the first run of } C \text{ corresponds to the last character of that run. Therefore, the number of minimal } C \text{-intervals of } A \text{ is } O(m). \]

We can compute $\text{RLE}(A) = a_1^{M_1} \cdots a_m^{M_m}$ and $\text{RLE}(C) = c_1^{K_1} \cdots c_k^{K_k}$ in $O(M + K)$ time. What remains is to show that the forward/backward search procedure described above to compute all minimal $C$-intervals of $A$ can be implemented in $O(MK)$ time. The pseudo-code of the algorithm described is shown in Algorithm 1.

In the forward search, we scan $\text{RLE}(A)$ to find a right minimal $C$-interval by greedily matching the runs of $\text{RLE}(C)$ to $\text{RLE}(A)$. We maintain the character $c_q$ and exponent rest of the first run $c_q^{\text{rest}}$ of $\text{RLE}(C')$, where $C'$ is the suffix of $C$ that is not yet matched. When comparing a run $a_p^{M_p}$ of $\text{RLE}(A)$ and $c_q^{\text{rest}}$, if the characters are different (i.e., $a_p \neq c_q$), we know that the entire run $a_p^{M_p}$ will not match and thus we can consider the next run of $A$. Suppose the characters are the same. Then, if $M_p < \text{rest}$, the entire run $a_p^{M_p}$ of $A$ is matched, and we can consider the next run $a_{p+1}^{M_p}$ of $A$. Also, rest can be updated accordingly in constant time by simple arithmetic. Furthermore, since $c_q = a_p \neq a_{p+1}$, we can in fact skip to the next run $a_{p+1}^{M_p}$. If $M_p \geq \text{rest}$, the entire run $c_q^{\text{rest}}$ is matched, and we consider the next run $c_{q+1}^{K_{q+1}}$ of $C$. Also, since $a_p = c_q \neq c_{q+1}$, we can skip the rest of $a_{p+1}^{M_p}$ and consider the next run $a_{p+1}^{M_p}$ of $A$. Thus, we spend only constant time for each run of $A$ that is scanned in the forward search. The same holds for the backward search.

To finish the proof, we show that the total number of times that each run of $A$ is scanned in the procedure is bounded by $O(K)$, i.e., the number of minimal $C$-intervals of $A$ that intersects with a given run $a_p^{M_p}$ of $A$ is $O(K)$. Since $|\text{RLE}(C)| > 1$, a minimal $C$-interval cannot be contained in $a_p^{M_p}$. Thus, for a minimal $C$-interval to intersect with the run $a_p^{M_p}$, it must cross either the left boundary of the run, or the right boundary of the run. For a minimal $C$-interval to cross the left boundary of the run, it must be that for some non-empty strings $u, v$ such that $C = uv$, $u$ occurs as a subsequence in $a_1^{M_1} \cdots a_{p-1}^{M_{p-1}}$ and $v$ occurs as a
Algorithm 1: computing all minimal $C$-intervals of $A$. 

Input: strings $A$ and $C$

if $M_p \geq rest$ then

$q \leftarrow q + 1$;
if $q < 1$ then $s_t \leftarrow M_{1,p} - rest + 1$;
else $p \leftarrow p - 1$; $rest \leftarrow K_q$;
else $rest \leftarrow rest - M_p$; $p \leftarrow p - 2$;

$p \leftarrow p + 1$; $q \leftarrow 1$; $rest \leftarrow K_1 - rest + 1$;

return $[s_1,f_1], \ldots , [s_l,f_l]$;

end

subsequence in $a_p^{M_p} \cdots a_m^{M_m}$. The minimal $C$-interval corresponds to the union of the left minimal $u$-interval ending at the left boundary of the run and the right minimal $v$-interval starting at the left boundary of the run and is thus unique for $u,v$. Similar arguments also hold for minimal $C$-intervals that cross the right boundary of $a_p^{M_p}$. Since there are only $K - 1$ choices for $u,v$, the claim holds, thus proving the Lemma.

In Deorowicz's algorithm, two DP tables were computed for Step 2, which took $O(MN)$ time. For our algorithm, we use a compressed representation of the DP table for $A$ and $B$, proposed by Bunke and Csirik [4], instead of the normal DP table. We note that Bunke and Csirik actually solved the edit distance problem when the cost is 1 for insertion and deletion, and 2 for substitution, but this easily translates to LCS: $L^{pref}(i,j) = (i+j - ED^{pref}(i,j))/2$, where $ED^{pref}(i,j)$ denotes the edit distance with such costs, between $A[1..i]$ and $B[1..j]$. 

\( \text{ED} \)
**Figure 1** An example of a compressed $L^{pref}$ DP table for strings $A = \text{bbbbaaa}$ and $B = \text{aaaabbbbaa}$.

**Definition 5** ([4]). Let $A$, $B$ be strings of length $M$, $N$ respectively, where $RLE(A) = a_1^{M_1} \cdots a_m^{M_m}$ and $RLE(B) = b_1^{N_1} \cdots b_n^{N_n}$. The compressed DP table (cDP table) of $A, B$ is an $O(mN + nM)$-space compressed representation of the DP table of $A, B$ which holds only the values of the DP table for $(M_{1,p}, j)$ and $(i, N_{1,q})$, where, $1 \leq i \leq M$, $1 \leq j \leq N$, $1 \leq p \leq m$, $1 \leq q \leq n$, $M_{1,p} = M_1 + \cdots + M_p$, $N_{1,q} = N_1 + \cdots + N_q$.

Figure 1 illustrates the values stored in the cDP table for strings $A = \text{bbbbaaa}$, $B = \text{aaaabbbbaa}$. Note that although the figure depicts a sparsely filled table of size $M \times N$, the values are actually stored in two (completely filled) tables: one of size $m \times N$, holding the values of $(M_{1,p}, j)$, and another of size $M \times n$, holding the values of $(i, N_{1,q})$, for a total of $O(mN + nM)$ space. Below are results adapted from [4] we will use.

**Lemma 6** ([4, Theorem 7]). Let $A$ and $B$ be any strings where $|A| = M$, $|B| = N$, $|RLE(A)| = m$ and $|RLE(B)| = n$. The compressed DP table of $A$ and $B$ can be computed in $O(mN + nM)$ time and space.

**Lemma 7** ([4, Lemma 3]). Let $\alpha \in \Sigma$ and let $A$ and $B$ be any strings where $|A| = M$ and $|B| = N$. For any integer $d \geq 1$, if $A[M - d + 1..M] = B[N - d + 1..N] = \alpha^d$, then $L^{pref}(M, N) = L^{pref}(M - d, N - d) + d$.

**Lemma 8** ([4, Lemma 5]). Let $\alpha, \beta \in \Sigma$, $\alpha \neq \beta$ and let $A$ and $B$ be any strings where $|A| = M$ and $|B| = N$. For any integers $d \geq 1$ and $d' \geq 1$, if $A[M - d + 1..M] = \alpha^d$ and $B[N - d' + 1..N] = \beta^{d'}$ then $L^{pref}(M, N) = \max \{L^{pref}(M - d, N), L^{pref}(M, N - d')\}$.

From Lemmas 7 and 8, we easily obtain the following Lemma 9.

**Lemma 9.** Let $A$ and $B$ be any strings. Any entry of the DP table of $A$ and $B$ can be retrieved in $O(1)$ time by using the compressed DP table of $A$ and $B$.

From Lemma 6, we can compute in $O(mN + nM)$ time, two cDP tables of $A, B$ which respectively hold the values of $L^{pref}(M_{1,p}, j)$, $L^{pref}(i, N_{1,q})$ and $L^{suf}(M_{1,p}, j)$, $L^{suf}(i, N_{1,q})$, each of them taking $O(mN + nM)$ space. From Lemma 9, we can obtain $L^{pref}(i, j)$, $L^{suf}(i, j)$ for any $i$ and $j$ in $O(1)$ time. Actually, to make Lemma 9 work, we also need to be able to convert the indexes between DP and cDP in constant time, i.e., for any $1 \leq p \leq m$, $1 \leq q \leq n$, the values $M_{1,p}$ and $N_{1,q}$, and for any $1 \leq i \leq M$, $1 \leq j \leq N$, the largest $p, q$ such that $M_{1,p} \leq i$, $N_{1,q} \leq j$. This is easy to do by preparing some arrays in $O(M + N)$ time and space.

Now we are ready to show the running time of our algorithm for the case $|RLE(C)| > 1$. We can compute $RLE(A), RLE(B), RLE(C)$ from $A, B, C$ in $O(M + N + K)$ time. In Step 1,
we have from Lemma 4, that the number of all minimal C-intervals of \( A, B \) are respectively \( O(m) \) and \( O(n) \), and can be computed in \( O(M + N + mK + nK) \) time. For the preprocessing of Step 2, we build the cDP tables holding the values of \( L^{\text{pref}}(i, j) \), \( L^{\text{suf}}(i, j) \) for \( 1 \leq i \leq M, 1 \leq j \leq N \), which can be computed in \( O(mN + nM) \) time and space from Lemma 6. With these tables, we can obtain for any \( i, j \), the values \( L^{\text{pref}}(i, j) \), \( L^{\text{suf}}(i, j) \) in constant time from Lemma 9. Since there are \( O mn \) pairs of a minimal C-interval of \( A \) and a minimal C-interval of \( B \), the total time for Step 2, i.e. computing \( L^{\text{pref}} \) and \( L^{\text{suf}} \) for each of the pairs, is \( O(mn) \). Since \( n \leq N, m \leq M \), and we can assume that \( K \leq M, N \), the total time is \( O(mN + nM) \). Thus Theorem 3 holds.

### 3.2.2 Case \( |RLE(C)| = 1 \)

Next, we consider the case where \( |RLE(C)| = 1 \), and \( C \) consists of only one run.

**Theorem 10.** Let \( A, B, C \) be any strings and let \( |A| = M \), \( |B| = N \), \( |RLE(A)| = m \) and \( |RLE(B)| = n \). If \( |RLE(C)| = 1 \), we can compute the length of an STR-IC-LCS of \( A, B, C \) in \( O(mn + nM) \) time.

For Step 1, we compute all minimal C-intervals of \( A \) and \( B \) by Lemma 11. Note the difference from Lemma 4 in the case of \( |RLE(C)| > 1 \).

**Lemma 11.** If \( |RLE(C)| = 1 \), the number of minimal C-intervals of \( A \) and \( B \) are \( O(M) \) and \( O(N) \), respectively, and these can be enumerated in \( O(M) \) and \( O(N) \) time, respectively.

**Proof.** Let \( \alpha \in \Sigma, C = \alpha^K \), and let \( M_\alpha \) be the number of times that \( \alpha \) occurs in \( A \). Then the number of minimal C-intervals of \( A \) is \( M_\alpha - K + 1 \in O(M) \). The minimal C-intervals can be enumerated in \( O(M) \) time by checking all positions of \( \alpha \) in \( A \). The same applies to \( B \). ▲

From Lemma 11, we can see that the number of pairs of minimal C-intervals of \( A \) and \( B \) can be \( \Theta(MN) \), and we cannot afford to consider all of those pairs for Step 2. We overcome this problem as follows. Let \( U = \{[s_1, f_1], \ldots, [s_l, f_l]\} \) be the set of all minimal C-intervals of \( A \). Consider the partition \( G(1), \ldots, G(g) \) of \( U \) which are the equivalence classes induced by the following equivalence relation on \( U \): For any \( 1 \leq p \leq q \leq m \) and \( [s_x, f_x], [s_y, f_y] \in U \),

\[
[s_x, f_x] \equiv [s_y, f_y] \iff M_{1, p-1} < s_x, s_y \leq M_{1, p} \text{ and } M_{1, q-1} < f_x, f_y \leq M_{1, q},
\]

where, \( M_{1, 0} = 0 \). In other words, \( [s_x, f_x] \) and \( [s_y, f_y] \) are in the same equivalence class if they start in the same run, and end in the same run. Noticing that minimal C-intervals cannot be completely contained in another minimal C-interval, we can assume that for \( 1 \leq h < h' \leq g \), \( [s_x, f_x] \in G(h) \) and \( [s_y, f_y] \in G(h') \), we have \( s_x < s_y \) and \( f_x < f_y \).

**Lemma 12.** Let \( G(1), \ldots, G(g) \) be the partition of the set \( U \) of all minimal C-intervals of \( A \) induced by the equivalence relation \( (1) \). Then, \( g \in O(m) \).

**Proof.** Let \( 1 \leq x < y \leq l \) and \( 2 \leq h \leq g \). For any \( [s_x, f_x] \in G(h - 1) \) and \( [s_y, f_y] \in G(h) \), let \( 1 \leq p \leq q \leq m \) satisfy \( M_{1, p-1} < s_x \leq M_{1, p}, M_{1, q-1} < f_x \leq M_{1, q} \). Since the intervals are not equivalent, either \( M_{1, p} < s_y \) or \( M_{1, q} < f_y \) must hold. Thus, \( g \in O(m) \). ▲

Equivalently for \( B \), we consider the set \( U' = \{[s'_1, f'_1], \ldots, [s'_l, f'_l]\} \) of all minimal C-intervals of \( B \), and the partition \( G'(1), \ldots, G'(g') \) of \( U' \) based on the analogous equivalence relation, where \( g' \in O(n) \).
For some $h$, let $[s_x, f_x], [s_y, f_y]$ be the minimal $C$-intervals in $G(h)$ with the smallest and largest start positions. Since by definition, $A[s_x] = \cdots = A[s_y] = A[f_x] = \cdots = A[f_y]$, we have $G(h) = \{[s_x, f_x], [s_x + 1, f_x + 1], \ldots, [s_y, f_y]\}$. The same can be said for $G'(h')$ of $B$.

From this observation, we can show the following Lemma 13.

**Lemma 13.** For any $1 \leq h \leq g$ and $1 \leq h' \leq g'$, let $[s, f], [s+d, f+d] \in G(h)$ and $[s', f'], [s'+d, f'+d] \in G'(h')$, for some positive integer $d$. Then,

$$L^{\text{pref}}(s-1, s'-1) + L^{\text{sufl}}(f+1, f'+1) = L^{\text{pref}}(s+d-1, s'+d-1) + L^{\text{sufl}}(f+d+1, f'+d+1).$$

**Proof.** Since $A[s..s+d] = A[f..f+d] = B[s'.s'+d] = B[f'.f'+d] = C[1]^d$, we have from Lemma 7, $L^{\text{pref}}(s+d-1, s'+d-1) + L^{\text{sufl}}(f+1, f'+1) = L^{\text{sufl}}(f+d+1, f'+d+1) + d$.

From Lemma 13, we can see that for any $(h, h') (1 \leq h \leq g, 1 \leq h' \leq g')$, we do not need to compute $L^{\text{pref}}(s-1, s'-1) + L^{\text{sufl}}(f+1, f'+1)$ for all pairs of $[s, f] \in G(h)$ and $[s', f'] \in G'(h')$. Let $G_{\text{min}}(h)$ and $G'_{\text{min}}(h')$ be the minimal $C$-intervals respectively in $G(h)$ and $G'(h')$ with the smallest starting position. Then, we only need to consider the combination of $G_{\text{min}}(h)$ with each of $[s', f'] \in G'(h')$, and the combination of each of $[s, f] \in G(h)$ with $G'_{\text{min}}(h')$. Therefore, of all combinations of minimal $C$-intervals in $U'$, we only need to consider for all $1 \leq h \leq g$ and $1 \leq h' \leq g'$, the combination of $G_{\text{min}}(h)$ with each of $U'$, and each of $U$ with $G'_{\text{min}}(h')$. The number of such combinations is clearly $O(mN + nM)$.

For example, consider $RLE(A) = a^3b^3a^4b^2a^1$, $RLE(B) = a^4b^3a^7b^3$, $RLE(C) = a^5$. For the minimal $C$-intervals of $A$, we have $G(1) = \{[1, 5]\}$, $G(2) = \{[2, 9]\}$, and $G(3) = \{[9, 15]\}$. For the minimal $C$-intervals of $B$, we have $G'(1) = \{[1, 8]\}$, $G'(2) = \{[5, 9]\}$, and $G'(3) = \{[6, 10]\}$. Also, $G_{\text{min}}(2) = [2, 9]$, $G'_{\text{min}}(2) = [5, 9]$. Figure 2 shows the lengths of the LCS of prefixes and suffixes for each combination between minimal $C$-intervals in $G(2)$ and $G'(2)$. The gray part is the values that are referred to. The values denoted inside parentheses are not stored in the cDP table, but each of them can be computed in $O(1)$ time from Lemma 9. Figure 3 shows the sum of the LCS of prefixes and suffixes corresponding to the gray part. Due to Lemma 13, the values along the diagonal are equal. Thus, for the combinations of minimal $C$-intervals in $G(2)$, $G'(2)$, we only need to consider the six combinations: $([2, 9],[5, 9]), ([2, 9],[6, 10]), ([2, 9],[7, 11]), ([3, 10],[5, 9]), ([4, 11],[5, 9]), ([5, 12],[5, 9])$.  

\[ \begin{array}{c|cccc|cccc} \hline & a & b & b & b & a & a & a & \cdots \\ \hline A & a & 1 & 1 & 1 & (1) & (1) & \cdots & \\ a & 1 & 1 & (2) & (2) & & & \\ a & 1 & (2) & (3) & & & & \\ a & 1 & 2 & & & & & \\ b & 1 & & & & & & \\ \hline B & a & 1 & (2) & (3) & & & \\ \hline \end{array} \]

\[ \begin{array}{c|cccc|cccc} \hline & a & a & a & b & b & b & \cdots & \\ \hline A & a & : & : & : & : & : & : & \\ a & : & : & : & : & : & : & 4 \\ a & : & : & : & : & : & : & \pdb{2} \\ a & : & : & : & : & : & : & \pdb{2} \\ b & \pdb{2} & 2 & 2 & 2 & 2 & 1 & \\ b & \pdb{2} & 2 & 2 & 2 & 2 & 1 & \\ a & \pdb{2} & 2 & 2 & 2 & 2 & 1 & \\ \hline B & : & : & : & : & : & : & : & \\ \hline \end{array} \]
Figure 3 Sum of the lengths of LCSs of corresponding prefixes and suffixes shown in Figure 2. Values along the diagonal are equal (each value is equal to the value to its upper left/lower right).

Now, we are ready to show the running time of our algorithm for the case $|RLE(C)| = 1$. We can compute $RLE(A)$, $RLE(B)$, $RLE(C)$ from $A$, $B$, $C$ in $O(M + N + K)$ time. There are respectively $O(M)$ and $O(N)$ minimal $C$-intervals of $A$ and $B$, and each of them can be assigned to one of the $O(m)$ and $O(n)$ equivalence classes $G$, $G'$, in total of $O(M + N)$ time. The preprocessing for the cDP table is the same as for the case of $|RLE(C)| > 1$, which can be done in $O(mN + nM)$ time. By Lemma 13, we can reduce the number of combinations of minimal $C$-intervals to consider to $O(mN + nM)$. Finally, from Lemma 9, the LCS lengths for each combination can be computed in $O(1)$ using the cDP table. Therefore, the total running time is $O(mN + nM)$, proving Theorem 10.

From Theorems 3 and 10, the following Theorem 14 holds. The pseudo-code for our proposed algorithm is shown in Algorithm 2.

**Theorem 14.** Let $A$, $B$, $C$ be any strings and let $|A| = M$, $|B| = N$, $|RLE(A)| = m$ and $|RLE(B)| = n$. We can compute the length of an STR-IC-LCS of $A$, $B$, $C$ in $O(mN + nM)$ time.

Although we only showed how to compute the length of an STR-IC-LCS, we note that the algorithm can be modified so as to obtain a RLE of an STR-IC-LCS in $O(m + n)$ time, provided that $RLE(C)$ is precomputed, simply by storing the minimal $C$-intervals $[s, f]$, $[s', f']$, respectively of $A$ and $B$, that maximizes $L_{\text{pref}}(s-1, s'-1) + L_{\text{suf}}(f+1, f'+1) + |C|$. From Lemmas 7 and 8, we can simulate a standard back-tracking of the DP table for obtaining LCSs with the cDP table to obtain RLE of the LCSs in $O(m + n)$ time. Finally an RLE of STR-IC-LCS can be obtained by combining the three RLE strings (the two LCSs with $RLE(C)$ in the middle), appropriately merging the boundary runs if necessary.

4 Conclusion

In this work, we proposed a new algorithm to solve the STR-IC-LCS problem using an RLE representation. We can compute the length of an STR-IC-LCS of strings $A$, $B$, $C$ in $O(mN + nM)$ time and space using this algorithm, where $|A| = M$, $|B| = N$, $|RLE(A)| = m$ and $|RLE(B)| = n$. This result is better than Deorowicz’s $O(MN)$ time and space [7], which does not use RLE. If we want to know not only the length but also an STR-IC-LCS of $A$, $B$, $C$, we can retrieve it in $O(m + n)$ time.
Algorithm 2: Proposed $O(mN + Mn)$ time algorithm for STR-IC-LCS.

**Input:** strings A, B and C

**Output:** length of an STR-IC-LCS of A, B, C

// [s_x, f_x] : a minimal C-interval in A
// [s'_y, f'_y] : a minimal C-interval in B
// l, l' : number of minimal C-intervals in A, B respectively
// $G_{\text{min}}(h), G'_{\text{min}}(h')$ : minimum element in $G(h), G'(h')$ respectively
// $g, g'$ : number of sets G, G' respectively

1. Make compressed DP tables of A and B;
2. if $|RLE(C)| > 1$ then
3. Compute all minimal C-intervals $[s_1, f_1], \ldots, [s_l, f_l]$ of A and $[s'_1, f'_1], \ldots, [s'_p, f'_p]$ of B. (use Algorithm 1);
4. $L_{\text{max}} \leftarrow 0$;
5. for $x = 1$ to $l$ do
6. for $y = 1$ to $l'$ do
7. $L_{\text{sum}} \leftarrow L_{\text{pref}}(s_x - 1, s'_y - 1) + L_{\text{suf}}(f_x + 1, f'_y + 1)$;
8. if $L_{\text{max}} < L_{\text{sum}}$ then $L_{\text{max}} \leftarrow L_{\text{sum}}$;
9. else
10. $l \leftarrow 1 - K; g \leftarrow 1; G_{\text{min}}(1) \leftarrow 1$;

Abstract

We give a probabilistic analysis of parameters related to $\alpha$-gapped repeats and palindromes in random words, under both uniform and memoryless distributions (where letters have different probabilities, but are drawn independently). More precisely, we study the expected number of maximal $\alpha$-gapped patterns, as well as the expected length of the longest $\alpha$-gapped pattern in a random word.

1 Introduction

In this article, we are interested in the combinatorial aspects of the notion of $\alpha$-gapped repeat and $\alpha$-gapped palindromes [10, 7, 4]. An $\alpha$-gapped repeat in a word is a factor of the form $uvu$, where $u$ and $v$ are words with $|uv| \leq \alpha|u|$. More precisely, such a pattern is essentially a repetition of $u$, but the second occurrence is not too far away from the first one. The definition for palindromes is similar, as we are looking for factors of the form $uvw$ instead, where $v$ is the reverse of $u$. The study of gapped patterns (see also [1, 12]) finds most of its motivation in bioinformatics. Recent works show that these patterns can be found in linear time [11, 17, 6], and there cannot be more than a linear number of them [2, 7]. Note that $\alpha$-gapped repeats are also called fractional powers [16]: $uvw$ is an $\alpha$-gapped repeat if and only if it is a fractional power of $uv$ with exponent at least $1 + \alpha^{-1}$.

When looking at patterns in words, there are usually two main categories of questions: providing efficient algorithms to find a specific set of patterns and studying the combinatorics of words with a focus on the appearance (or avoidance) of these patterns. These two points of view are of course directly related, as insights on the combinatorial properties often yield ideas for building new efficient algorithms.

In the sequel, we propose a probabilistic analysis of parameters related to $\alpha$-gapped repeats and palindromes; more precisely, we answer the following questions:
- What is the expected number of $\alpha$-gapped patterns in a random word?
- What is the expected length of the longest $\alpha$-gapped pattern in a random word?

This only makes sense if one specifies what is meant by a random word, i.e., what the distribution on words is. We first consider the uniform distribution, which often serves as an introductory example for the techniques we use and can provide, for instance, useful elements for average analysis of algorithms, while still being mathematically tractable. We
also consider memoryless sources, which give a more general, yet simple distribution where all letters are not constrained to have identical frequencies. In this model, each letter is drawn independently following a fixed, but possibly biased, distribution on the alphabet. In particular, we exhibit a noteworthy behavior on the longest $\alpha$-gapped repeat: if each letter $a_i$ has probability $\pi_i$, then a long random word of length $n$ has about $\pi_n n$ occurrences of each letter $a_i$; however, in a long $\alpha$-gapped repeat $uu\pi$, the frequencies of the letters in the $u$ parts of the factor do not follow this typical distribution (see section 4.2).

Our work follows several other combinatorial and probabilistic results obtained for different kinds of patterns in words, such as the expected number of runs [14], the expected total run length [8], the expected number of distinct palindromic factors [15], etc. We use both techniques from analytic combinatorics, based on the definition of generating series for gapped patterns in words, as in [13], and classical discrete probabilities.

## 2 Preliminaries

For any two nonnegative integers $i, j$, let $[i, j]$ denote the integer interval $\{i, \ldots, j\}$. By convention, $[i, j] = \emptyset$ if $j < i$. Let also $[i]$ denote the integer interval $[1, i]$.

In the sequel we consider words on a finite alphabet $A$, of cardinality $k \geq 2$. We assume the reader is familiar with the classical definitions on words [3], such as prefixes, suffixes, and factors. For $w \in A^*$ of length $n$ and $i \in [n]$, let $w_i$ (or $w[i]$) denote the $i$-th letter of $w$, with the convention that positions start at 1. The last letter of $w$ is therefore $w_n$. Let also $w[i, j] = w_i \cdots w_j$ denote the factor of $w$ that starts at position $i$ and ends at position $j$, with $w[i, j] = \varepsilon$ if $i > j$ or if $i$ or $j$ is not in $[n]$. The factor of $w$ of length $\ell$ that starts at position $i$ is $w[i, i+\ell-1]$. For a given length $\ell$, a position $i$ in $w$ is valid if $i + \ell - 1 \leq n$.

A gapped repeat in a word $w$ of length $n$ is a triple $(i, u, v)$, where $i \in [n]$ and $u$ and $v$ are nonempty words, such that the factor of $w$ of length $|uvu|$ starting at position $i$ is $uvu$. For a given real $\alpha \geq 1$, it is an $\alpha$-gapped repeat if $|uv| \leq \alpha |u|$. A gapped repeat $(i, u, v)$ of $w$ is maximal if, when the positions exist, $w_{i-1} \neq w_{i+|uv|-1}$ and $w_{i+|uv|} \neq w_{i+|u|}$, i.e., the gapped repeat cannot be extended to the left or to the right.

Similar notions can be defined for palindromes. Under the same conditions for $i, u, v$, a triple $(i, u, v)$ is an $\alpha$-gapped palindrome if the factor of length $|uv\pi|$ starting at position $i$ in $w$ is $uv\pi$, where $\pi = u\pi_1 \cdots u_1$ denote the reverse of $u$. It is an $\alpha$-gapped palindrome if $|uv| \leq \alpha |u|$ and maximal if $u_{i-1} \neq u_{i+|uv|}$ (when they exist) and either $|v| = 1$ or $v_1 \neq v_{|v|}$.

**Example 1.** Consider $w = aababbbababbab$ and $\alpha = 2$. The triple $(4, ab, bb)$ is an $\alpha$-gapped repeat, but it is not maximal since it can be extended to the left to form $(3, bab, b)$.

**Remark.** In the sequel, we only consider $\alpha$-gapped patterns (repeats or palindromes) for rational $\alpha \geq 1$. This really matters for Section 3 only, as the other results hold for any real $\alpha \geq 1$. It is also convenient to consider $\beta := \alpha - 1$ in most computations, as it changes the condition into $|u| \leq \beta |v|$, and we therefore use this notation from now on.

The uniform distribution on a finite set $E$ is the probability $\pi$ defined for all $e \in E$ by $\pi(e) = \frac{1}{|E|}$. By a slight abuse of notation, we will speak of the uniform distribution on $A^*$ to denote the sequence $(\pi_n)_{n \geq 0}$ of uniform distributions on $A^n$. For instance, if $A = \{a, b, c\}$, then each element of $A^n$ has probability $3^{-n}$ under this distribution.

Another very classical distribution on $A^n$ is the memoryless distribution of probability $\pi$, where $\pi$ is a probability on the alphabet $A$. Under this distribution, the probability of a word $w = w_1 \cdots w_n \in A^n$ is $\PP_n(w) = \pi(w_1) \cdots \pi(w_n)$. This distribution can also be seen as generating each letter of the word independently, following $\pi$. 

It is convenient to fix a total order $a_1 < \ldots < a_k$ on $A$ and to define $\pi_i = \pi(a_i)$ for all $i \in [k]$. We also see $\pi$ as a vector $\vec{\pi} = (\pi_1, \ldots, \pi_k)$ of $[0, 1]^k$. This notation will be used repeatedly in the sequel.

3 Number of gapped patterns

In this section, we compute the average number of maximal $\alpha$-gapped patterns (repeats or palindromes) in random words of length $n$ under a memoryless distribution. Our main tool is writing exact generating functions, which happen to be rational fractions; the asymptotic behavior is then obtained by using standard theorems of analytic combinatorics [5].

3.1 Framework

Let $A = \{a_1, \ldots, a_k\}$ be an alphabet and, for every $i \in [k]$, let $z_i$ be a formal variable (associated with the letter $a_i$). To each word $w \in A^*$ we associate a monomial $c(w) = z_{i_1}^{w_{i_1}} \cdots z_{i_k}^{w_{i_k}}$, where $|w|_i$ is the number of occurrences of the letter $a_i$ in $w$. In other words, the mapping $c$ allows us to consider words as in the abelian world, where letters commute. Let $\vec{z} = (z_1, \ldots, z_k)$. If $X$ is a set of words, its formal power series $X(\vec{z})$ is defined as the formal sum of the monomials associated with its words: $X(\vec{z}) = \sum_{w \in X} c(w)$. As we shall see, this power series is a tool of choice to study the probabilistic properties of the set $X$.

First, the symbolic method [5] can be used to build $X(\vec{z})$, directly from a nonambiguous regular description of $X$: if $X$, $Y$ and $Z$ are three sets of words whose respective series are $X(\vec{z})$, $Y(\vec{z})$ and $Z(\vec{z})$, then

- if $X$ is the disjoint union of $Y$ and $Z$, then $X(\vec{z}) = Y(\vec{z}) + Z(\vec{z})$;
- if $X$ is the nonambiguous concatenation of $Y$ and $Z$, then $X(\vec{z}) = Y(\vec{z}) Z(\vec{z})$;
- if $X$ is the nonambiguous Kleene star of $Y$, then $X(\vec{z}) = \frac{1}{1 - Y(\vec{z})}$.

Second, for a given probability $\vec{\pi} = (\pi_1, \ldots, \pi_k)$ on $A$, one can build the formal power series in a single variable $\overline{X}(z)$, by substituting $\pi_i z$ to each $z_i$. After the substitution, the contribution of each word of length $n$ to the coefficient of $z^n$ in $\overline{X}(z)$, in the memoryless model, is exactly its probability. By marking a certain set of patterns with a copy of the alphabet, one can effectively multiply the contribution of a word by its number of patterns, and hence compute the expected number of such patterns using this technique (another approach is to control the unambiguity of the description [13]). Once $\overline{X}(z)$ is known, analytic combinatorics can be used to estimate the quantities under study.

Let us illustrate this technique on a toy example. Assume that we want to compute the expected number of occurrences of the pattern $aba$ in a random word of length $n$ under the memoryless distribution on the alphabet $\{a, b\}$, with $\pi_a = \frac{1}{3}$ and $\pi_b = \frac{2}{3}$. Observe that the word $w = bbaababaab$ contains two (overlapping) occurrences of the pattern. The marking technique consists in distinguishing these two occurrences by using another alphabet, say $\{\bar{a}, \bar{b}\}$, for the letters of the pattern. The associated regular language is $L = (a + b)^* \overline{aba}(a + b)^*$. The two words $w = abababaab$ and $w = babababaab$ correspond to $w$, which therefore contributes twice, as the pattern occurs twice. Using the symbolic method directly yields that the generating series of $L$ is

$$L(\bar{z}) = \frac{1}{1 - (z_a + z_b)} \cdot \bar{z}_a \bar{z}_b z_a \cdot \frac{1}{1 - (z_a + z_b)} = \frac{z_a^2 z_b}{(1 - z_a - z_b)^2}.$$

1 For readability, we use $\pi_a$, $\pi_b$, $z_1$ and $z_2$ instead of $\pi_1$, $\pi_2$, $z_1$ and $z_2$. 

CPM 2017
We now use this general framework to compute the expected number of maximal word of length \( n \). Then, we compute in turn, forces us to distinguish between the subcases interested in gapped repeats) or patterns. To simplify the notations, for any positive integer \( i \), yielding the (natural) estimate of \( \frac{2n}{77} \) occurrences on average.

### 3.2 Generating series for the expected number of patterns

We now use this general framework to compute the expected number of maximal \( \alpha \)-gapped patterns. To simplify the notations, for any positive integer \( i \) and any vector \( \vec{z} \), let \( N_i(\vec{z}) = z_1^i + \ldots + z_k^i \). In particular, \( N_1(\vec{z}) = z_1 + \ldots + z_k \).

A gapped pattern is equivalent to a triple of words \((u, v, u')\), with a condition \( u' = u \) (for gapped repeats) or \( u' = \pi \) (for gapped palindromes), and a length condition \( 1 \leq |v| \leq \beta |u| \), which we rewrite into the equivalent \( |u| \geq |v|/\beta \) and \( |v| \geq 1 \). Because we are ultimately interested in maximal patterns, we need to keep track of the first and last letters of \( v \); this, in turn, forces us to distinguish between the subcases \(|v| = 1\) and \(|v| \geq 2\).

In the simpler case \(|v| = 1\), a pattern is just given by a single letter \( a \in A \), and an arbitrary word \( u \) of length at least \( \lceil 1/\beta \rceil \). The generating series for words of length at least \( \ell \) is \( N_1(\vec{z})^{\ell}/(1 - N_1(\vec{z})) \). In our patterns, the letters of \( u \) are to be counted twice, once in \( u \) and once in \( u' \). This is taken into account by just changing \( N_1(\vec{z}) \) into \( N_2(\vec{z}) \) into the formula. Hence, the generating series for \( \alpha \)-gapped patterns with \( v = a_i \) is

\[
U_\alpha(\vec{z}) = \frac{(N_1(\vec{z}) - 2N_2(\vec{z}) + N_3(\vec{z}))N_2(\vec{z})^{1/\beta}}{(1 - N_1(\vec{z}))^2(1 - N_2(\vec{z}))}.
\]

For gapped palindromes, there is a condition on the prefix and suffix when they are both nonempty: the last letter of the prefix must be different from the first letter of the suffix. This leads to multiplying the generating series for all patterns by the generating series for this set of pairs of words, which is \( \frac{1-N_2(\vec{z})}{1-N_1(\vec{z})} \). We thus get as the generating series for all words with a marked maximal \( \alpha \)-gapped palindrome having a gap of length exactly 1,
We now turn to the case $|v| \geq 2$. For any two letters $a_i$ and $a_j$, we consider the possible gapped patterns (see Figure 1) such that $v$ starts with $a_i$ and ends with $a_j$ (for maximal gapped palindromes, an additional condition is $i \neq j$). Let $\ell + 2$ be the length of such a word $v$; the $\alpha$-gapped condition is thus $|u| \geq (\ell + 2)/\beta$. Writing $\beta = p/q$ with positive integers $p$ and $q$, and writing the Euclidean division of $\ell$ by $p$ as $\ell = tp + m$, the condition becomes $|u| \geq tq + (m + 2)/\beta$.

Thus, in the pattern $uva'$, $u$ is obtained by concatenation of $t$ arbitrary words of length $q$, plus one arbitrary word of length $[(m + 2)/\beta]$, plus an arbitrary (possibly empty) word; and $v$ starts with $a_i$, concatenated with $t$ arbitrary words of length $p$, plus one arbitrary word of length $m$, and ends with $a_j$. In the pattern composition, the composition of $u$ has to be counted twice since $a'$ also contributes and has the same composition. Summing over all possible values of $t$ and $m$, we get the generating series for all $\alpha$-gapped patterns such that $v$ starts with $a_i$ and ends with $a_j$:

$$G_{\alpha,i,j}(z) = \frac{z_iz_jQ_\alpha(z)}{(1 - Q_2(z))(1 - N_1(z)^p N_2(z)^q)},$$

with $Q_\alpha(z) = \sum_{m=0}^{p-1} N_1(z)^m N_2(z)^{(m+2)/\beta}$.

Writing the generating functions for all words with a marked maximal gapped pattern again corresponds to adding a prefix and suffix, but leads to different generating functions for repeats and palindromes because the conditions on the suffix and prefix are slightly different.

For gapped repeats, both the prefix and the suffix can be empty, or an arbitrary word that does not end with $a_j$ (for the prefix), or that does not start with $a_i$ (for the suffix). This is done by multiplying the generating series $G_{\alpha,i,j}(z)$ by $(1 - z_i)(1 - z_j)/(1 - N_1(z))^2$.

Taking the sum over all possible $j$ yields that the generating series of all words with a marked maximal $\alpha$-gapped repeat and $|v| \geq 2$ is

$$V_\alpha(z) = \frac{(N_1(z) - N_2(z))^2 Q_\alpha(z)}{(1 - N_1(z))^2(1 - N_2(z))(1 - N_1(z)^p N_2(z)^q)}.$$ 

For gapped palindromes, maximality induces two conditions. First the last letter of $v$ must be different from its first letter; this is taken into account by summing $G_{\alpha,i,j}(z)$ over all possible $i \neq j$. Second, the prefix and suffix must also satisfy the same conditions as for the case $|v| = 1$, which leads to multiply by $\frac{1 - N_2(z)}{(1 - N_1(z))^2}$ as before. Hence, the generating series of all words with a marked maximal $\alpha$-gapped palindrome and $|v| \geq 2$ is

$$\overline{V}_\alpha(z) = \frac{(N_1(z)^2 - N_2(z)) Q_\alpha(z)}{(1 - N_1(z))^2(1 - N_1(z)^p N_2(z)^q)}.$$ 

We can now proceed with the substitution $z_i = \pi_i z$, which changes $N_1(z)$ into $z$, $N_2(z)$ into $\lambda_2 z^2$ and $N_3(z)$ into $\lambda_3 z^3$, with $\lambda_j = \sum z_i$. Let $\chi(w)$ (resp. $\xi(w)$) denote the number of maximal $\alpha$-gapped repeats (resp. palindromes) in a word $w$. Let $R(z) = \sum_w \chi(w) \overline{z}^{[w]}$ and $P(z) = \sum_w \xi(w) \overline{z}^{[w]}$ be the generating series of the expectations of $\chi$ and $\xi$, that is, the coefficients of $z^n$ of $R(z)$ and $P(z)$ are $E_n[\chi]$ and $E_n[\xi]$, respectively. These series $R(z)$ and $P(z)$ are obtained by
the previous substitutions $z_i \rightarrow \pi_i z$ from the series $U_\alpha(z) + V_\alpha(z)$ and $\overline{U}_\alpha(z) + \overline{V}_\alpha(z)$, respectively. From the computations above, we obtain the following statement.

**Theorem 2.** For $\beta = \alpha - 1 - \frac{p}{q}$, the series $R(z)$ and $P(z)$ for the memoryless model of probability $\bar{\pi}$ are given by

$$R(z) = \frac{(z - 2\lambda_2 z^2 + \lambda_3 z^3)\lambda_2^{[1/\beta]} z^{[1/\beta]}}{(1 - z)^2(1 - \lambda_2 z^2)} + \frac{(z - \lambda_2 z^2)^2 \overline{Q}_\alpha(z)}{(1 - z)^2(1 - \lambda_2 z^2)(1 - \lambda_2^q z^{p+2q})},$$

$$P(z) = \frac{\lambda_2^{[1/\beta]} z^{1+2[1/\beta]}}{(1 - z)^2} + \frac{(z^2 - \lambda_2 z^2) \overline{Q}_\alpha(z)}{(1 - z)^2(1 - \lambda_2^q z^{p+2q})},$$

with

$$\overline{Q}_\alpha(z) = \sum_{j=0}^{p-1} \lambda_2^{(j+2)/\beta} z^{j+2[(j+2)/\beta]}, \quad \lambda_2 = \sum_{i=1}^{k} \pi_i^2, \quad \text{and} \quad \lambda_3 = \sum_{i=1}^{k} \pi_i^3.$$

### 3.3 From generating series to asymptotics

Analytic combinatorics links asymptotic behavior of counting sequences to singularities of the corresponding generating functions, viewed as analytic functions of a complex variable. For rational generating series of one variable, as in Theorem 2, the situation is quite simple, and we use this simplified version of the Transfer Theorem [5] for rational functions:

**Theorem 3 (Simplified Transfer Theorem [5]).** Assume $A(z) = F(z)(1 - z)^{-\ell}$, where $\ell$ is a positive integer, $F(z)$ is a rational function with no pole in the closed disc of radius 1 and $F(1) \neq 0$. Then the $n$-th coefficient of $A(z)$ is asymptotically equivalent to $\frac{F(1)}{(\ell-1)!} n^{\ell-1}$.

The series $R(z)$ and $P(z)$ of Theorem 2 both have a dominant pole of order 2 at $z = 1$. Applying Theorem 3 yields the following statement. Note that, though the generating series $R(z)$ and $P(z)$ are different, they lead to the same asymptotics for the coefficients; the difference is in lower order terms.

**Theorem 4.** Under the memoryless distribution of probability $\bar{\pi}$, and for any rational $\alpha = 1 + p/q$, the expected number of maximal $\alpha$-gapped repeats (respectively, palindromes) in a random word of length $n$ is asymptotically equivalent to $r_\alpha n$ (respectively, $p_\alpha n$) defined by

$$r_\alpha = \frac{(1 - 2\lambda_2 + \lambda_3)\lambda_2^{[q/p]}}{1 - \lambda_2} \sum_{j=2}^{p+1} \lambda_2^{[jq/p]} + \left(1 - \lambda_2^q\right) \sum_{j=2}^{p+1} \lambda_2^{[jq/p]}, \quad \text{and} \quad p_\alpha = \frac{(1 - \lambda_2^q)}{1 - \lambda_2^2} \sum_{j=2}^{p+1} \lambda_2^{[jq/p]}.$$

In particular, when $\alpha$ is a positive integer, these reduce to

$$r_\alpha = (\alpha - 1)\lambda_2 + \frac{\lambda_2(\lambda_3 - \lambda_2^2)}{1 - \lambda_2^2} \quad \text{and} \quad p_\alpha = (\alpha - 1)\lambda_2 + \lambda_2^2.$$

For the uniform distribution, we have $\lambda_2 = 1/k$ and $\lambda_3 = 1/k^2$, yielding the following result.

**Corollary 5.** For the uniform distribution on an alphabet of size $k \geq 2$, we have

$$r_\alpha = \frac{k-1}{k} \left(k^{-[q/p]} + \frac{\sum_{j=2}^{p+1} k^{-[jq/p]}}{1 - k^{-q}}\right) \quad \text{and} \quad p_\alpha = r_\alpha + k^{-1-[q/p]}.$$

In particular, if $\alpha$ is a positive integer, then $r_\alpha = \frac{\alpha-1}{k}$ and $p_\alpha = \frac{\alpha-1}{k} + \frac{1}{k^2}$. 

Remark. As a function of $\alpha = 1 + \frac{p}{q}$, the value of $r_\alpha$ is not very regular. It is increasing, as expected, but there are some large variations when reaching a value with a small denominator (typically integers or half-integers). This also gives hints on the difficulty of giving a formula if $\alpha$ is not rational. Some examples are given in the table below, for $k = 4$.

4 Longest pattern

In this section we focus on the typical and expected length of the longest $\alpha$-gapped patterns (repeat or palindrome) in a random word. Contrarily to the previous section, our analysis relies on discrete probabilities rather than on generating series.

Let $L_n$ denote the random variable associated with the length of the longest $\alpha$-gapped patterns in a random word of length $n$. We first focus on the uniform distribution, in order to introduce the main techniques of this section. For memoryless distributions, the computations are more involved, but the general idea remains the same.

If $X_n$ is a random variable, we say that it is concentrated around its mean if there exists a sequence $(\nu_n)_{n \geq 1}$ that tends to 0 such that $\Pr(|X_n - \mathbb{E}[X_n]| > \nu_n \mathbb{E}[X_n]) \xrightarrow{n \to \infty} 0$.

In this whole section, whenever we say that some property holds with asymptotic probability 1, the property implicitly depends on some integer $n$, which denotes the length of the random words considered; and we mean that, as $n$ goes to infinity, the probability tends to 1. The details in the text typically make it possible to derive a more explicit bound on the speed of convergence.

4.1 Uniform distribution

We establish the following theorem. Its proof is obtained by computing tight lower and upper bounds for the typical value of $L_n$, for the uniform distribution.

Theorem 6. For the uniform distribution on words of length $n$, on an alphabet of size $k$, the expected length of the longest $\alpha$-gapped repeat (or palindrome) is asymptotically equivalent to $(\alpha + 1) \log_k n$. Moreover, the random variable $L_n$ is concentrated around its mean.

Observe that a longest $\alpha$-gapped repeat is necessarily maximal. Moreover, the proof is exactly the same for palindromes, so we focus on repeats only.

To establish the lower bound, we prove that with asymptotic probability 1 there is an $\alpha$-gapped repeat of length $t_0$ in a random word of length $n$, where $t_0$ is a well chosen value, which is asymptotically equivalent to $(\alpha + 1) \log_k n$. This property is proved to hold by just looking for $\alpha$-gapped repeats lying at very specific positions: the word is split into roughly $n/t_0$ factors of length $t_0$, and we only compute the probability that at least one of these factors is an $\alpha$-gapped repeat of a particular $|v|/|u|$ ratio. This fairly rough estimation is enough to establish a lower bound that is asymptotically tight.

For any $\ell \geq 1$, let $\mathcal{M}_\beta(\ell)$ denote the set of words of the form $uvu$, with $u \in A^\ell$ and $v \in A^{[\beta \ell]}$. The set $\mathcal{M}_\beta(\ell)$ therefore contains all the $\alpha$-gapped repeats where $u$ has size $\ell$ and $v$ is of maximal length. Let $t_0 = \lceil \log_k n - 2 \log_k \log_k n \rceil$. Every word of $\mathcal{M}_\beta(t_0)$ has length $t_0 = 2t_0 + \lfloor \beta t_0 \rfloor$, and $t_0$ is asymptotically equivalent to $(\alpha + 1) \log_k n$, as required.

The probability for an element of $\mathcal{M}_\beta(t_0)$ to be a factor of a random word of length $n$ is exactly the probability that, for some $i \in [n]$, the factor of length $t_0$ starting at position $i$ belongs to $\mathcal{M}_\beta(t_0)$. Thus, it is at least the probability that the factor of length $t_0$ starting
at position $1 + j t_0$ is in $\mathcal{M}_\beta(t_0)$ for some $j \geq 1$ such that $(j + 1) t_0 \leq n$. For such a given $j$, the probability that the factor starting at position $1 + j t_0$ is in $\mathcal{M}_\beta(t_0)$ is $k^{-t_0}$, since $|\mathcal{M}_\beta(t_0)| = k^{t_0 - 2|\beta|}$ and each possible factor has probability $k^{-t_0 - 2|\beta|}$. Since the integer intervals $[1 + j t_0, (j + 1) t_0]$ do not overlap, the factors they define are independent, and the probability that none of them is in $\mathcal{M}_\beta(t_0)$ is $(1 - k^{-t_0})^{n/t_0}$. Therefore, with probability at least $1 - (1 - k^{-t_0})^{n/t_0}$, a random word of length $n$ contains an $\alpha$-gapped repeat of length $t_0$.

Straightforward computations yield that $(1 - k^{-t_0})^{n/t_0} \leq \exp(- \log_\alpha n)$, which tends to 0 as $n \to \infty$. Thus, with asymptotic probability 1, a random uniform word of length $n$ contains an $\alpha$-gapped repeat of length $t_0$, which is asymptotically equivalent to $(\alpha + 1) \log_\alpha n$.

We now proceed with the upper bound. Let $\mathcal{R}_\beta(t)$ denote the set of all words $uvw$ such that $|uvw| = t$ and $|v| \leq \beta |w|$. The set $\mathcal{R}_\beta(t)$ contains all the possible $\alpha$-gapped repeats of length $t$. Observe that, by summing over all the possible lengths $\ell \leq u$, we have

$$\mathcal{R}_\beta(t) = \{t - \ell \leq k^{t-\ell} \leq k^{t-\ell + (2+\beta)}\sum_{j=0}^{\infty} k^{-j} \leq 2^{k^{(\beta+1)\ell/(\beta+2)}}.\}

Let $t_1 = \lceil (\beta + 2) \log_\alpha n + 2(\beta + 2) \log_\alpha \log_\alpha n \rceil + 1$. The probability that a random word contains a factor in $\mathcal{R}_\beta(t_1)$ at a given valid position is $|\mathcal{R}_\beta(t_1)| k^{-t_1} \leq 2k^{-t_1/(\beta+2)}$. Since the number of valid positions is no more than $n$, by the union bound, the probability that a uniform random word of length $n$ contains an element of $\mathcal{R}_\beta(t_1)$ (as a factor in any position) is at most $2n k^{-t_1/(\beta+2)}$. These computations also hold if one substitutes $t_1 + i$ for $t_1$. This yields that the probability that a uniform random word of length $n$ contains an element of $\mathcal{R}_\beta(t_1 + i)$ is bounded from above by $2^{k^{-t_1/(\beta+2)}}$.

Using the union bound again, we sum these bounds for $i \geq 0$, and obtain that, with asymptotic probability 1, a uniform random word of length $n$ contains no $\alpha$-gapped repeat of length greater than or equal to $t_1$, which is asymptotically equivalent to $(\alpha + 1) \log_\alpha n$.

A bit more is required to estimate the expectation of $L_n$, but this can be easily done from the computations above: they yield that the contribution to the expectation of the values that are not between $t_0$ and $t_1$ is negligible, and $t_0 \sim t_1 \sim (\alpha + 1) \log_\alpha n$. The concentration around the mean can be proved by taking any sequence $\nu_n$ that tends to 0 and such that $\nu_n \log_\alpha n \log_\alpha \log_\alpha n$ tends to infinity.

### 4.2 Memoryless sources

In this section, we associate to each letter $a_i \in A = \{a_1, \ldots, a_k\}$ a probability $\pi_i = p(a_i)$ as described in Section 2. We assume all these probabilities to be positive (otherwise, reduce the alphabet size accordingly).

From the probability $\pi$, we build another probability $\bar{\pi}$ proportional to the square of $\pi$: for every $i \in [k]$, $\tau_i = \pi_i^2 / \lambda_2$, where $\lambda_2 = \sum_{i \in [k]} \pi_i^2$ is the coincidence probability of $\pi$ (as in Section 3). The result for memoryless sources, which generalizes Theorem 6, is the following.

**Theorem 7.** For the memoryless source of probability $\bar{\pi}$, the expected length of the longest $\alpha$-gapped repeat (or palindrome) in a random word of length $n$ is asymptotically $\mathbb{E}[L_n] \sim (\alpha + 1) \log_\alpha \lambda_2 n$, where $\lambda_2 = \sum_{i \in [k]} \pi_i^2$. Moreover, $L_n$ is concentrated around its mean.

Though it follows the same main ideas as in the proof of Theorem 6, the proof of Theorem 7 is more technical. Due to lack of space, we only focus on the main steps in this extended abstract. We will focus on the most probable words, and the most probable longest
\( \alpha \)-gapped repeat. For this purpose, for a probability vector \( \vec{s} \) on \( A \) and \( \delta \geq 0 \), we consider the set \( \mathcal{W}_n(\vec{s}, \delta) \) of words whose letters roughly follow the distribution of \( \vec{s} \), defined by
\[
\mathcal{W}_n(\vec{s}, \delta) = \left\{ u \in \mathcal{A}^n : \| u|_a - s(a) n \| \leq \delta, \ \forall a \in A \right\}.
\]
To establish the lower bound, we define the set \( \mathcal{M}_\beta(\vec{\pi}, \ell) \) of \( \alpha \)-gapped repeats \( uvu \) where the letters are distributed following \( \vec{\pi} \) in \( v \) and following \( \vec{\tau} \) in \( u \). More formally:
\[
\mathcal{M}_\beta(\vec{\pi}, \ell) = \left\{ uvu \in A^* : u \in \mathcal{W}_l(\vec{\pi}, \sqrt{\log n}) \text{ and } v \in \mathcal{W}_{l|v|}(\vec{\tau}, \sqrt{\log n}) \right\}.
\]
The set \( \mathcal{M}_\beta(\vec{\pi}, \ell) \) will play the same role as the set \( \mathcal{M}_\beta(\ell) \) of the previous section. They do not coincide if the distribution is uniform, but they still have the same order of size.

We now proceed with the lower bound. We define \( \ell_0 \) and \( t_0 \) by
\[
\ell_0 = \left\lfloor \frac{\log n}{\log(1/\lambda_2)} \right\rfloor \quad \text{and} \quad t_0 = 2\ell_0 + \lfloor \beta \ell_0 \rfloor,
\]
then prove that long random words have a factor in \( \mathcal{M}_\beta(\vec{\pi}, \ell_0) \) with high probability.

For this purpose, we need to estimate the probability that a factor of length \( t_0 \) at a given position is in \( \mathcal{M}_\beta(\vec{\pi}, \ell_0) \). The computations are done as follows. Let \( \vec{n} = (n_1, \ldots, n_k) \) with \( n_1 + \ldots + n_k = \ell_0 \) and let \( \vec{m} = (m_1, \ldots, m_k) \) with \( m_1 + \ldots + m_k = \lfloor \beta \ell_0 \rfloor \). We are interested in the set of words \( \mathcal{E}(\vec{n}, \vec{m}) \), with fixed compositions for \( u \) and \( v \), defined by
\[
\mathcal{E}(\vec{n}, \vec{m}) = \left\{ uvu : |u|_{a_i} = n_i \text{ and } |v|_{a_i} = m_i, \ \forall i \in [k] \right\}.
\]
Observe that \( \mathcal{M}_\beta(\ell_0) \) can be written as a union of \( \mathcal{E}(\vec{n}, \vec{m}) \) for properly chosen ranges for \( \vec{n} \) and \( \vec{m} \). The probability that the factor of length \( t_0 \) at a given valid position lies in \( \mathcal{E}(\vec{n}, \vec{m}) \) is
\[
\mathbb{P}_t(\mathcal{E}(\vec{n}, \vec{m})) = \left( \frac{\ell_0}{n_1, \ldots, n_k} \right) \prod_{i \in [k]} \pi_{i}^{2n_i} \left( \frac{\lfloor \beta \ell_0 \rfloor}{m_1, \ldots, m_k} \right) \prod_{i \in [k]} \pi_{i}^{m_i}.
\]
By estimating this quantity and summing for all \( \vec{n} \) and \( \vec{m} \) such that \( \mathcal{E}(\vec{n}, \vec{m}) \subseteq \mathcal{M}_\beta(\ell_0) \), we obtain the probability that the factor of length \( t_0 \) at a given valid position not being in \( \mathcal{M}_\beta(\vec{\pi}, \ell_0) \) is \( O\left(\frac{1}{\log n}\right) \). At this point, the proof continues exactly as in Section 4.1.

We now turn to the upper bound. As in Section 4.1 let \( \mathcal{R}_\beta(t) \) be the set of all \( uvu \) such that \( |uvu| = t \) and \( 1 \leq |v| \leq \beta |u| \). We want to compute an upper bound for the probability that the factor of length \( t \) at a given valid position lies in \( \mathcal{R}_\beta(t) \).

We need to partition the set \( \mathcal{R}_\beta(t) \) for our computations. Let \( \vec{\ell} = (\ell_1, \ldots, \ell_k) \) be a vector of non-negative integers such that \( N_1(\vec{\ell}) = \ell_1 + \cdots + \ell_k = \ell \). Let \( \mathcal{R}_\beta(\vec{\ell}, t) \) be the set of all words \( uvu \) such that \( |uvu| = t \) and \( |u|_{a_i} = \ell_i \) for every \( i \in [k] \). Observe that \( \mathcal{R}_\beta(t) \) can be written as the following disjoint union:
\[
\mathcal{R}_\beta(t) = \bigcup_{\ell_0 = \lfloor t/(\beta+2) \rfloor}^{\lfloor (t-1)/2 \rfloor} \bigcup_{N_1(\vec{\ell}) = \ell} \mathcal{R}(\vec{\ell}, t).
\]
Moreover, \( \mathbb{P}_t(\mathcal{R}(\vec{\ell}, t)) = \ell_0^{\ell_0} \prod_{i \in [k]} \pi_{i}^{2\ell_i} \). But \( \sum_{N_1(\vec{\ell}) = \ell} \ell_0^{\ell_0} \prod_{i \in [k]} \pi_{i}^{2\ell_i} = 1 \), as it is the sum of the probabilities of all the words of length \( \ell \) for the memoryless distribution of probability vector \( \vec{\tau} \). Hence, \( \mathbb{P}_t(\cup_{N_1(\vec{\ell}) = \ell} \mathcal{R}(\vec{\ell}, t)) = \lambda_2^\ell \). Therefore, \( \mathbb{P}_t(\mathcal{R}_\beta(t)) \leq t \lambda_2^{t/(\beta+2)}. \) In particular, for \( t_1 = \left\lfloor (\beta + 2) \log_{1//\lambda_2} n + 3(\beta + 2) \log_{1//\lambda_2} \log n \right\rfloor \), we have
\[
\mathbb{P}(\mathcal{R}_\beta(t_1 + i)) \leq \frac{2 \lambda_2^{t/(\beta+2)}}{\log n},
\]
and the proof continues as in the uniform case.
Gapped Pattern Statistics

**Remark.** As a byproduct of the proof, we obtain the following interesting result on the probabilistic nature of the longest \(\alpha\)-gapped repeat. Though a sufficiently large random word in the memoryless model contains roughly a proportion \(\pi_t\) of each letter \(a_i\), the letters are distributed differently in the arms (the \(u\)'s of \(uvu\)) of a typical longest \(\alpha\)-gapped repeat: the proportion of each letter is roughly \(\pi_i\) instead of \(\pi_t\). This phenomenon is completely hidden in the uniform case, where \(\pi_i = \pi_t = 1/k\) for every \(i \in [k]\).

5 A remark on the number of distinct factors

In [15], Rubinchik and Shur estimated the expected number of distinct palindromes in a random word: these factors are counted only once, even if they have multiple occurrences. They established that for the uniform distribution, a random word contains \(\Theta(\sqrt{n})\) distinct palindromes, and several refinements of this result.

In this short section we explain how their proof can be extended to estimate the expected number of distinct \(\alpha\)-gapped repeats and palindromes, for the uniform distribution. There is no new idea, one just has to take care of the possibilities for the additional \(v\) part in the pattern. The result, however, is interesting on its own. It is stated as followed.

**Theorem 8.** For the uniform distribution over words of length \(n\), the expected number of distinct \(\alpha\)-gapped repeats (or palindromes) is in \(\Theta(n^{\alpha/(\alpha+1)})\).

We only consider repeats in our proof sketch; gapped palindromes are treated the same way. The lower bound is obtained using Guibas and Odlyzko’s result on pattern avoidance [9]: the number of words of length \(n\) that avoid a given pattern \(w\) of length \(m > 3\) is equal to \(C_w \theta_w + O(1.7^n)\). In [15], the authors prove that the constants are maximal when \(w = a^m\):

\[
\theta_w \leq \theta_{a^m} = k \left( 1 - \frac{k-1}{k^{m+1}} + O \left( \frac{m}{k^{2m+2}} \right) \right) \text{ and } C_w \leq C_{a^m} = 1 + O \left( \frac{m}{k^m} \right). \tag{1}
\]

Let \(\mathcal{S}_{\beta}(n)\) be the set of all \(uvu\) such that \(|u| = \ell = \left\lfloor \frac{1}{\beta+1} \log_k n \right\rfloor\) and \(|v| = \lfloor \beta \ell \rfloor\). Let \(m = 2\ell + \lfloor \beta \ell \rfloor\). As a direct application of Equation (1), for a given \(w \in \mathcal{S}_{\beta}(n)\), the probability that a random word of length \(n\) avoids \(w\) satisfies

\[
P_n(\text{avoiding } w) \leq \left( 1 - \frac{k-1}{k^{m+1}} + O \left( \frac{m}{k^{2m+2}} \right) \right)^n \left( 1 + O \left( \frac{m}{k^m} \right) \right),
\]

which is at most \(C\) for some positive constant \(C < 1\) and \(n\) sufficiently large (for our choice of \(\ell\), and thus of \(m\)). Hence, the probability for \(w\) to be a factor in a random word of length \(n\) is at least \(1 - C\), and by linearity of the expectation, the expected number of distinct \(\alpha\)-gapped repeats is greater than or equal to \((1 - C)|\mathcal{S}_{\beta}(n)| = (1 - C)k^{m-\ell} = \Omega(n^{\alpha/(\alpha+1)})\).

For the upper bound, let \(\mathcal{R}_{\beta}(t)\) denote all the \(uvu\) such that \(|uvu| = t\) and \(|v| \leq \beta|u|\). Let also \(t_0 = \lfloor \log_k n \rfloor\). We count differently the \(\alpha\)-gapped repeats, depending on whether they are shorter or longer than \(t_0\).

We count all the \(\alpha\)-gapped repeats of length at most \(t_0\) as contributing to the upper bound. By summing over all possible values for the length \(\ell\) of the arms, we have

\[
|R_{\beta}(t)| = \sum_{\ell = \lfloor t/(\beta+1) \rfloor}^{\lfloor (t-1)/2 \rfloor} k^{t-\ell} \leq k^t \sum_{\ell = \lfloor t/(\beta+1) \rfloor}^{\infty} k^{t-\ell} \leq 2k^{(\beta+1)t/(\beta+2)}.
\]

Hence,

\[
\sum_{t=1}^{t_0} |R_{\beta}(t)| \leq \sum_{t=1}^{t_0} 2k^{(\beta+1)t/(\beta+2)} \leq 4k^{(\beta+1)t_0/(\beta+2)} \leq 4n^{\alpha/(\alpha+1)}.
\]
To obtain an upper bound for the expected number of patterns of length greater than \(t_0\), we observe as in [15] that the probability for a given \(\alpha\)-gapped repeat \(uvu\) to be a factor is at most the expected number of occurrences of \(uvu\). As we shall see, this rough upper bound is enough to conclude. Let \(R_\beta(t, \ell)\) be the set of \(uvu\) such that \(|uvu| = t\), \(|u| = \ell\) and \(|v| \leq \beta \ell\). The probability that there is pattern of \(R_\beta(t, \ell)\) at a given valid position in a random word is \(k^{-\ell}\). Hence, the expected number of occurrences of such patterns is at most \(nk^{-\ell}\), for given \(t\) and \(\ell\). By summing over all \(t > t_0\) and all valid \(\ell\) for each \(t\) we obtain the following upper bound:

\[
\sum_{t=t_0}^{n} k^{-\ell} \leq \sum_{t=t_0}^{\lfloor t/2 \rfloor} 2k^{-t/(\beta+2)} \leq 4k^{-t_0/(\beta+2)} \leq 4n^{\alpha/((\alpha+1))}.
\]

Combining both results, for short and long \(\alpha\)-gapped repeats, we get that the expected number of distinct such factors is bounded from above by \(8n^{\alpha/((\alpha+1))}\), concluding the proof.

\[\blacktriangleright\text{Remark.}\] Theorem 8 also holds for maximal patterns. The proof simply needs to be adapted for the lower bound, and there are sufficiently many of them to obtain the same result.

6 Conclusions

In this article we establish results about some statistics of random words related to the notion of \(\alpha\)-gapped patterns, for both the uniform and memoryless distributions. We propose different techniques, generating series and discrete probabilities, to provide some tools for further analysis of statistics of interest. Amongst them, if would be natural to consider gapped patterns as a whole, \(i.e.\) if \(uvu = u'v'u'\) then it is considered as one pattern instead of two different ones.

The biased distribution on letters in the arms of a typical \(\alpha\)-gapped pattern, in the memoryless model, is something worth noticing (see Section 4.2). It may provide some leverage for speeding up algorithms, though the difference might be too thin to be exploited.

Finally, generalizing Theorem 8 to memoryless proves quite difficult. This is ongoing work, and the techniques involved are more advanced than what is presented in this article.

Abstract
Given a string on an integer alphabet, we present an algorithm that computes the set of all distinct squares belonging to this string in time linear in the string length. As an application, we show how to compute the tree topology of the minimal augmented suffix tree in linear time. Besides from that, we elaborate an algorithm computing the longest previous table in a succinct representation using compressed working space.

1 Introduction

A square is a string of the form SS, where S is some non-empty string. It is well-known that a string of length n contains at most \( n^2/4 \) squares. This bound is the number of all squares, i.e., we count multiple occurrences of the same square, too. If we consider the number of all distinct squares, i.e., we count exactly one occurrence of each square, then it becomes linear in n: The first linear upper bound was given by Fraenkel and Simpson [17] who proved that a string of length n contains at most \( 2n \) distinct squares. Later, Ilie [26] showed the slightly improved bound of \( 2n - \Theta(\lg n) \). Recently, Deza et al. [10] refined this bound to \( \lceil 11n/6 \rceil \). In the light of these results one may wonder whether future results will “converge” to the upper bound of n: The distinct square conjecture [17, 27] is that a string of length n contains at most n distinct squares; this number is known to be independent of the alphabet size [37].

However, there still is a big gap between the best known bound and the conjecture. While studying a combinatorial problem like this, it is natural to think about ways to actually compute the exact number.

This article focuses on a computational problem on distinct squares, namely, we wish to compute (a compact representation of) the set of all distinct squares in a given string. Gusfield and Stoye [23] tackled this problem with an algorithm running in \( O(n\sigma_T) \) time, where \( \sigma_T \) denotes the number of different characters contained in the input text T of length n.

* This work was mainly done while Dominik Köppl visited Kyushu University in Japan under the support by the JSPS Summer Program SP16005. Hideo Bannai and Shunsuke Inenaga were supported in part by JSPS KAKENHI Grant Numbers JP26280003, JP16H02783, JP17H01697.
Although its running time is optimal $O(n)$ for a constant alphabet, it becomes $O(n^2)$ for a large alphabet since $\sigma_T$ can be as large as $O(n)$.

We present an algorithm (Section 4.1) that computes this set in $O(n)$ time for a given string of length $n$ over an integer alphabet of size $n^{O(1)}$. Like Gusfield and Stoye, we can use the computed set to decorate the suffix tree with all squares (Section 5.1). As an application, we provide an algorithm that computes the tree topology of the minimal augmented suffix tree $T[1]$ in linear time (Section 5.2). The fastest known algorithm computing this tree topology takes $O(n \lg n)$ time [5].

For our approach, we additionally need the longest previous factor table [18, 8]. As a side result of independent interest, we show in Section 3 how to store this table in $2n + o(n)$ bits, and give an algorithm that computes it using compressed working space.

2 Definitions

Our computational model is the word RAM model with word size $\Omega(\lg n)$ for some natural number $n$. Let $\Sigma$ denote an integer alphabet of size $\sigma = |\Sigma| = n^{O(1)}$. An element $w$ in $\Sigma^*$ is called a string, and $|w|$ denotes its length. We denote the $i$-th character of $w$ with $w[i]$, for $1 \leq i \leq |w|$. When $w$ is represented by the concatenation of $x, y, z \in \Sigma^*$, i.e., $w = xyz$, then $x$, $y$ and $z$ are called a prefix, substring and suffix of $w$, respectively. For $1 \leq i \leq j \leq |w|$, let $w[i..j]$ denote the substring of $w$ that begins at position $i$ and ends at position $j$ in $w$.

The longest common prefix (LCP) of two strings is the longest prefix shared by both strings. The longest common extension (LCE) query asks for the longest common prefix of two suffixes of the same string. The time for an LCE query is denoted by $t_{LCE}$.

A factorization of a string $T$ is a sequence of non-empty substrings of $T$ such that the concatenations of the substrings is $T$. Each substring in the factorization is called a factor.

In the rest of this paper, we take a string $T$ of length $n > 0$, and call it the text. We assume that $T[n] = \$$ is a special character that appears nowhere else in $T$, so that no suffix of $T$ is a prefix of another suffix of $T$. We further assume that $T$ is read-only; accessing a character costs constant time. We sometimes need the reverse of $T$, which is given by the concatenation $T[n - 1] \cdots T[1]$, i.e., $T[n] = T[n - 1] \cdots T[1]|\$$.

The suffix tree of $T$ is the tree obtained by compacting the trie of all suffixes of $T$; it has $n$ leaves and at most $n - 1$ internal nodes. The leaf corresponding to the $i$-th suffix $T[i..n]$ is labeled with $i$. Each edge $e$ is associated with a non-empty substring $x$ of $T$ called the edge label of $e$. Each edge label $x$ is represented by tuple $(i, \ell)$ of integers such that $T[i..i+\ell-1] = x$. This way the suffix tree of $T$ takes $O(n)$ words of space, and it can be computed in $O(n)$ time for strings of length $n$ over an integer alphabet of size $n^{O(1)}$ [11].

The string label of a node $v$ is defined as the concatenation of all edge labels on the path from the root to $v$; the string depth of a node is the length of its string label.

SA and ISA denote the suffix array and the inverse suffix array of $T$, respectively [36]. The access time to an element of SA is denoted by $t_{SA}$. LCP is an array such that $LCP[i]$ is the length of the longest common prefix of $T[SA[i]..n]$ and $T[SA[i] - 1..n]$ for $i = 2, \ldots, n$. For our convenience, we define $LCP[1] := 0$. The arrays SA, ISA, and LCP can be constructed in $O(n)$ time [30, 32, 31].

A range minimum query (RMQ) asks for the smallest value in a sub-array of an integer array. There are data structures that can answer RMQs on an integer array of length $n$ in constant time while taking $2n + o(n)$ bits of space [15]. An LCE query for the suffixes $T[s..n]$ and $T[t..n]$ can be answered with an RMQ data structure on LCP with the range $[\min(ISA[s], ISA[t]) + 1..\max(ISA[s], ISA[t])]$ in constant time.
A bit vector is a string on the binary alphabet \{0, 1\}. A select query on a bit vector asks the position of the \(i\)-th ‘0’ or ‘1’ in the bit vector. There is a data structure that can be built in \(O(n)\) time with \(O(n)\) bits of working space such that it takes \(o(n)\) bits on top of the bit vector, and can answer a select query in constant time [6].

We identify occurrences of substrings with their position and length in the text, i.e., if \(x\) is a substring of \(T\), then there is an \(i\) with \(1 \leq i \leq n\) and an \(\ell\) with \(0 \leq \ell \leq n - i + 1\) such that \(T[i..i + \ell - 1] = x\). In the following, we will represent the occurrences of substrings by tuples of position and length. When storing these tuples in a set, we call the set distinct, if there are no two tuples \((i, \ell)\) and \((i', \ell')\) such that \(T[i..i + \ell - 1] = T[i'..i' + \ell' - 1]\). A special kind of substring is a square: A square is a string of the form \(SS\) for \(S \in \Sigma^+\); we call \(S\) and \(|S|\) the root and the period of the square \(SS\), respectively. Like with substrings, we can generate a set containing some occurrences of squares. A set of all distinct squares is a distinct set of occurrences of squares that is maximal under inclusion.

### 3 A Compact Representation of the LPF Array

The longest previous factor table LPF of \(T\) is formally defined as

\[
\text{LPF}[j] := \max \{\ell \mid \text{there exists an } i \in [1..j - 1] \text{ such that } T[i..i + \ell - 1] = T[j..j + \ell - 1]\}.
\]

It is useful for computing the Lempel-Ziv factorization of \(T = f_1 \cdots f_z\), which is defined as \(f_i = T[k..k + \max(1, \text{LPF}[k])]\) with \(k := \sum_{j=1}^{i-1} |f_j| + 1\) for \(1 \leq i \leq z\).

In the following, we will use the text \(T = ababaababa\$\) as our running example whose LPF array is represented by the small numbers above the characters. The Lempel-Ziv factorization of \(T\) is given by \(a | b | a | ba | aa | baba | \$\), where the small numbers denote the factor indices, and the vertical bars denote the factor borders.

**Corollary 1.** Given LPF, we can compute the Lempel-Ziv factorization in \(O(n)\) time. If the factorization consists of \(z\) factors, the factorization can be represented by an array of \(z \lg n\) bits, where the \(x\)-th entry stores the beginning of the \(x\)-th factor. Alternatively, it can be represented by a bit vector of length \(n\) in which we mark the factor beginnings. A select data structure on top of the bit vector can return the length and the position of a factor in constant time.

Since we will need LPF in Section 4, we are interested in the time and space bounds for computing LPF. We start with the (to the best of our knowledge) state of the art algorithm with respect to time and space requirements.

**Lemma 2** ([9, Theorem 1]). Given SA and LCP, we can compute LPF in \(O(n \lg n)\) time. Besides the output space of \(n \lg n\) bits, we only need constant working space.

Apart from this algorithm, we are only aware of some practical improvements [40, 28].

Let us consider the size of LCP needed in Lemma 2. Sadakane [41] showed a \(2n + o(n)\)-bits representation of LCP. Thereto he stores the permuted longest-common-prefix array PLCP defined as \(\text{PLCP}[\text{SA}[i]] = \text{LCP}[i]\) in a bit vector in the following way (also described in [13]): Since \(\text{PLCP}[1] + 1, \text{PLCP}[2] + 2, \ldots, \text{PLCP}[n] + n\) is a non-decreasing sequence with \(1 \leq \text{PLCP}[1] + 1 \leq \text{PLCP}[n] + n = n\) (since the terminal \$\) is a unique character in \(T\) the values \(I[1] := \text{PLCP}[1]\) and \(I[i] := \text{PLCP}[i] - \text{PLCP}[i - 1] + 1\) \((2 \leq i \leq n)\) are non-negative. By writing \(I[i]\) in the unary code \(\sigma(0^{|I[i]|})\) to a bit vector \(S\) subsequently for each \(2 \leq i \leq n\), we can compute \(\text{PLCP}[i] = \text{select}_1(S, i) - 2i\) and \(\text{LCP}[i] = \text{select}_1(S, \text{SA}[i]) - 2\text{SA}[i]\). Moreover, \(\sum_{i=1}^{n} I[i] \leq n\) and therefore \(S\) is of length at most \(2n\).
22:4 Computing All Distinct Squares in Linear Time for Integer Alphabets

Table 1 Algorithms computing LPF; space is counted in bits. The output space $|\text{LPF}|$ is not considered as working space. $0 < \epsilon \leq 1$ is a constant.

| algorithm          | time        | working space   | $|\text{LPF}|$ |
|--------------------|-------------|-----------------|-------------|
| Lemma 2,[9]        | $O(n t_{SA})$ | $|\text{SA}| + |\text{LCP}| + O(\lg n)$ | $n \lg n$ |
| Corollary 3,[35, 24] | $O(n)$     | $n \lg n + 2n + O(\lg n)$ | $n \lg n$ |
| Lemma 6,[34]      | $O(n/\epsilon)$ | $(1 + \epsilon)n \lg n + O(n)$ | $2n + o(n)$ |
| Lemma 6,[16]      | $O(n t_{SA})$ | $O(n \lg \sigma)$ | $2n + o(n)$ |

By using Sadakane’s LCP-representation, we get LPF with the algorithm of Crochemore et al. [9] in the following time and space bounds:

- **Corollary 3.** Having SA and LCP stored in $n \lg n$ bits (this allows $t_{SA} = O(1)$) and $2n + o(n)$ bits, respectively, we can compute LPF with $O(\lg n)$ additional bits of working space (not counting the space for LPF) in $O(n)$ time.

By plugging in a suffix array construction algorithm like the in-place construction algorithm by Goto [21], we get the bounds shown in Table 1.

Although this result seems compelling, this approach stores SA and LPF in plain arrays (the former for getting constant time access). In the following, we will show that the LPF array can be stored more compactly. We start with a new representation of LPF, for which we use the same trick as for PLCP due to the following property (which is crucial for squeezing PLCP into $2n + o(n)$ bits).

- **Lemma 4.** $n - j + 1 \geq \text{LPF}[j] \geq \text{LPF}[j - 1] - 1$ for $2 \leq j \leq n$.

  **Proof.** There is an $i$ with $1 \leq i < j - 1$ such that $T[i..i + \text{LPF}[j - 1] - 1] = T[j - 1..j - 1 + \text{LPF}[j - 1] - 1]$. Hence $T[i + 1..i + \text{LPF}[j - 1] - 1] = T[j..j - 1 + \text{LPF}[j - 1] - 1]$.

We conclude that the sequence $\text{LPF}[1] + 1, \text{LPF}[2] + 2, \ldots, \text{LPF}[n] + n$ is non-decreasing with $1 \leq \text{LPF}[1] + 1 \leq \text{LPF}[n] + n \leq n$. We immediately get:

- **Corollary 5.** LPF can be represented by a bit vector with a select data structure such that accessing an LPF value can be performed in constant time. The data structures use $2n + o(n)$ bits.

To get a better working space bound, we have to come up with a new algorithm since the algorithm of Lemma 2 creates a plain array to get constant time random write-access for computing the entries of LPF. To this end, we present two algorithms that compute LPF in this representation with the aid of the suffix tree. The two algorithms are derivatives of the algorithms [34, 16] that compute the Lempel-Ziv factorization, either in $O(n \lg \lg \sigma)$ time using $O(n \lg \sigma)$ bits, or in $O(n/\epsilon^2)$ time using $(1 + \epsilon)n \lg n + O(n)$ bits, for a constant $0 < \epsilon \leq 1$. The current bottleneck of both algorithms is the suffix tree implementation with respect to space and time. Due to current achievements [39, 35], the algorithms now run in $O(n)$ time using $O(n \lg \sigma)$ bits, or in $O(n/\epsilon)$ time using $(1 + \epsilon)n \lg n + O(n)$ bits, respectively.

We aim at building the LPF-representation of Corollary 5 directly such that we do not need to allocate the plain LPF array using $n \lg n$ bits in the first place. To this end we create a bit vector of length $2n$ and store the LPF values in it successively. In more detail, we follow the description of the Lempel-Ziv factorization algorithms presented in [34, 16]. There, the algorithms are divided into several passes. In each pass we successively visit leaves in text...
order (determined by the labels of the leaves). To compute LPF, we only have to do a single pass. Similarly to the first passes of the two Lempel-Ziv algorithms, we use a bit vector $B_v$ to mark already visited internal nodes. On visiting a leaf we climb up the tree until reaching the root or an already marked node. In the former case (we climbed up to the root) we output zero. In the latter case, we output the string depth of the marked node. By doing so, we have computed LPF[1..j] after having processed the leaf with label $j$.

Lemma 6. We can compute LPF in $O(n\ell_{SA})$ time with $O(n \log \sigma)$ bits of working space, or in $O(n/\epsilon)$ time using $(1 + \epsilon)n \log n + O(n)$ bits of working space, for a constant $0 < \epsilon \leq 1$. Both variants include the space of the output in their working spaces.

Proof. Computing the string depth of a node needs access to an RMQ data structure of LCP, and an access to SA. Both accesses can be emulated by the compressed suffix array in $t_{SA}$ time, given that we have computed PLCP in the above representation.

4 The Set of All Distinct Squares

Given a string $T$, our goal is to compute all distinct squares of $T$. Thereto we return a set of pairs, where each pair $(s, \ell)$ consists of a starting position $s$ and a length $\ell$ such that $T[s..s + \ell - 1]$ is the leftmost occurrence of a square. The size of this set is linear due to

Lemma 7 (Fraenkel and Simpson [17]). A string of length $n$ can contain at most $2n$ distinct squares.

We follow the approach of Gusfield and Stoye [23]. Their idea is to compute a set of squares (the set stores pairs of position and length like described in Section 2)

We can compute $\ell_{SA}$ time, given that we have computed $LPF$.

that every square of the text can be constructed by right-rotating a square of this set. A square $(k, \ell)$ is constructed by right-rotating a square $(i, \ell)$ with $i \leq k$ if each tuple $(i + j, \ell)$ with $1 \leq j \leq k - i$ represents a square $T[i + j..i + \ell + j - 1] = T[i + j..i + \ell - 1]T[i..i + j - 1]$.

The set of the leftmost occurrences of all squares is a set of all distinct squares. Unfortunately, the leftmost covering set computed in [23] is not necessarily a set of all distinct squares since (a) it does not have to be distinct, and (b) a square might be missing that can be constructed by right-rotating a square of the computed leftmost covering set.

For illustration, the squares of our running example $T = \text{ababaababa}$ are highlighted with bars. The set of all squares is $\{(1,4), (2,4), (5,2), (6,2), (7,4), (8,4)\}$. If we take the leftmost occurrences of all squares, we get $\{(1,4), (2,4), (5,2)\}$; this set comprises all squares marked by the solid bars, i.e., the dotted bars correspond to occurrences of squares that are not leftmost. In this example, the dotted bars form the set $\{(6,2), (7,4), (8,4)\}$, which is a set of all distinct squares. A leftmost covering set is $\{(1,4), (5,2)\}$.

Our goal is to compute the set of all leftmost occurrences directly by modifying the algorithm of [23]. To this end, we briefly review how their approach works: They compute their leftmost covering set by examining the borders between all Lempel-Ziv factors $f_1 \cdots f_x = T$. That is because of

1 It differs to the set we want to compute by the fact that they allow, among others, occurrences of the same square in their set.
Computing All Distinct Squares in Linear Time for Integer Alphabets

The leftmost occurrence of a square $T[i..i+2p-1]$ touches at least two Lempel-Ziv factors. Let $f_x$ ($1 \leq x \leq z$) be the factor that contains the center of the square $i+p-1$. Then either

(a) the square has its left end (position $i$) inside $f_x$ and its right end (position $i+2p-1$) inside $f_{x+1}$, or

(b) the left end of the square extends inside $f_{x-1}$ (or even further left). The right end can be contained inside $f_x$ or $f_{x+1}$.

Having a data structure for computing LCE queries on the text and on its inverse, they can probe at the borders of two consecutive factors whether there is a square. Roughly speaking, they have to check at most $|f_x| + |f_{x+1}|$ many periods at the borders of every two consecutive factors $f_x$ and $f_{x+1}$ due to the above lemma ($1 \leq x \leq z$, set $f_{z+1}$ to the empty string). This gives $\sum_{x=1}^z t_{\text{LCE}}(|f_x| + |f_{x+1}|) = O(n t_{\text{LCE}})$ time, during which they can compute a leftmost covering set $L$. Figure 1 visualizes how the checks are done. Applying the algorithm on our running example will yield the set $L = \{(1, 4), (5, 2), (7, 4)\}$. To transform this set into a set of all distinct squares, their algorithm runs the so-called Phase II that uses the suffix tree. It begins with computing the locations of the squares belonging to a subset $L' \subseteq L$ in the suffix tree in $O(n)$ time. This subset $L'$ is still guaranteed to be a leftmost covering set. Finally, their algorithm computes all distinct squares of the text by right-rotating the squares in $L'$. In their algorithm, the right-rotations are done by suffix link walks over the suffix tree. Their running time analysis is based on the fact that each node has at most $\sigma_T$ incoming suffix links, where $\sigma_T$ denotes the number of different characters occurring in the text $T$. Given that the number of distinct squares is linear, Phase II runs in $O(n \sigma_T)$ time.

4.1 Algorithm Computing the Set of All Distinct Squares

In the following, we will present our modification of the above sketched algorithm. To speed up the computation, we discard the idea of using the suffix links for right-rotating squares (i.e., we skip Phase II completely). Instead, we compute a list of all distinct squares directly. To this end, we show a modification of the sketched algorithm such that it outputs this list sorted first by the lengths (of the squares), and second by the starting position.

First, we want to show that we can change the original algorithm to output its leftmost covering set in the above described order. To this end, we iterate over all possible periods, and search not yet reported squares at all Lempel-Ziv borders, for each period. To achieve linear running time, we want to skip a factor $f_x$ when the period becomes longer than $|f_x| + |f_{x+1}|$. We can do this with an array $Z$ of $z \log z$ bits that is zero initialized. When the currently tested period $p$ exceeds $|f_x| + |f_{x+1}|$, we write $Z[x] \leftarrow \min \{y > x : |f_y| + |f_{y+1}| \geq p\}$ such
that $Z[x]$ refers to the next factor whose length is sufficiently large. By doing so, if $Z[x] \neq 0$, we can skip all factors $f_y$ with $y \in [x..Z[x] - 1]$ in constant time. This allows us running the modified algorithm still in linear time.

We have to show that the modified algorithm still computes the same set. To this end, let us fix the period $p$ (over which we iterate in the outer loop). By [23, Lemma 7], processing squares satisfying Lemma 8(1) before processing squares satisfying Lemma 8(2) (all squares have the same period $p$) produces the desired output for period $p$.

Finally, we show the modification that computes all distinct squares (instead of the original leftmost covering set). On a high level, we use an RMQ data structure on LPF to filter already found squares. The filtered squares are used to determine the leftmost occurrences of all squares by right-rotation. In more detail, we modify Algorithm 1 of [23] by filtering the squares in the following way (see Algorithm 1 in the full version [2]): For each period $p$, we use a bit vector $B$ marking the beginning positions of all found squares with period $p$. On reporting a square, we additionally mark its starting position in $B$. By doing so, an invariant of the algorithm below is that all right-rotated squares of a marked square are already reported.

Let us assume that we are searching for the leftmost occurrences of all squares whose periods are equal to $p$. Given the starting position $s$ of a square returned by [23, Algorithm 1], we consider the square $(s, 2p)$ and its right-rotations as candidates of our list: If $B[s] = 1$, then this square and its right-rotations have already been reported. Otherwise, we report $(s, 2p)$ if $\text{LPF}[s] < 2p$. In order to find the leftmost occurrences of all not yet reported right-rotated squares efficiently, we first compute the rightmost position $e$ of the repetition of period $p$ containing the square $(s, 2p)$ by an LCE query. Second, we check the interval $I := [s + 1..\min(s + p - 1, e - 2p + 1)]$ for the starting positions of the squares whose LPF values are less than $2p$. To this end, we perform an RMQ query on LPF to find the position $j$ whose LPF value is minimal in $I$. If LPF[$j$] $> 2p$, then there is no leftmost occurrence of a square with the period $p$ in the considered range. Otherwise, we report $(j, 2p)$ and recursively search for the text position with the minimal LPF value within the intervals $[s + 1..j - 1]$ and $[j + 1..\min(s + p - 1, e - 2p + 1)]$. In overall, the time of the recursion is bounded by twice the number of distinct squares starting in the interval $I$, since a recursion step terminates if it could not report any square.

**Theorem 9.** Given an LCE data structure with $t_{LCE}$ access time and LPF, we can compute all distinct squares in $O(nt_{LCE} + \text{occ}) = O(nt_{LCE})$ time, where $\text{occ}$ is the number of distinct squares.

**Proof.** We show that the returned list is the list of all distinct squares. No square occurs in the list twice since we only report the occurrence of a square $(i, \ell)$ if $\text{LPF}[i] < \ell$. Assume that there is a square missing in the list; let $(i, \ell)$ be its leftmost occurrence. There is a square $(j, \ell)$ reported by the (original) algorithm [23] such that $i - \ell/2 < j \leq i$ and right-rotating $(j, \ell)$ yields $(i, \ell)$. Since we right-rotate all found squares, we obviously have reported $(j, \ell)$.

The occ term in the running time is dominated by the $nt_{LCE}$ term due to Lemma 7.

The next corollary, which is immediate from Theorem 9, yields the main result.

**Corollary 10.** Given a string $T$ of length $n$ over an integer alphabet of size $n^{O(1)}$, we can compute all distinct squares in $T$ in $O(n)$ time.
4.2 Need for RMQ on LPF

Our algorithm performs right-rotations of a square \((s, 2p)\) with an RMQ on the interval \(I := [s + 1, \min(s + p - 1, e - 2p + 1)]\), where \(e\) is the last position of the maximal repetition of period \(p\) that contains the square. Without an RMQ data structure, we could linearly scan all LPF values in \(I\), giving \(O(p) = O(n)\) time. We cannot do better since the LPF values are arbitrary in general. For instance, consider the text \(T = \text{abaaababaaabaaa}\$. The text aligned with LPF is shown in the table below.

The square \(abaaabaa\) has two occurrences starting at positions 1 and 10. The square \(baaabaaa\) at position 11 is found by right-rotating the occurrence of \(abaaabaa\) at position 10. It is found by a linear scan over LPF or an RMQ on LPF. A slight modification of this example can change the LPF values around this occurrence. This shows that we cannot perform a shortcut in general (like stopping the search when the LPF value is at least twice as large as \(p\)).

4.3 Practical Evaluation

We have implemented the algorithm computing the leftmost occurrences of all squares in C++11 [33]. The primary focus was on the execution time, rather than on a small memory footprint: We have deliberately chosen plain 32-bit integer arrays for storing all array data structures like SA, LCP and LPF. These data structures are constructed as follows: First, we generate SA with divsufsort [38]. Subsequently, we generate LCP with the \(\Phi\)-algorithm [29], and LPF with the simple algorithm of [9, Proposition 1]. Finally, we use the bit vector class and the RMQ data structure provided by the sdsl-lite library [20]. In practice, it makes sense to use an RMQ only for very large LCP values and periods (i.e., RMQs on LPF) due to its long execution time. For small values, we naively compared characters, or scanned LPF linearly.

We ran the algorithm on all 200MiB collections of the Pizza&Chili Corpus [12]. The Pizza&Chili Corpus is divided in a real text corpus with the prefix \(\text{pc}\), and in a repetitive corpus with the prefix \(\text{pcr}\). The experiments were conducted on a machine with 32 GB of RAM and an Intel® Xeon® CPU E3-1271 v3. The operating system was a 64-bit version of Ubuntu Linux 14.04 with the kernel version 3.13. We used a single execution thread for the experiments. The source code was compiled using the GNU compiler g++ 6.2.0 with the compile flags -O3 -march=native -DNDEBUG.

Table 2 shows the running times of the algorithm on the described datasets. It seems that large factors tend to slow down the computation, since the algorithm has to check all periods up to \(\max_x(|f_x| + |f_{x+1}|)\). This seems to have more impact on the running time than the number of Lempel-Ziv factors \(z\).

4.4 Online Variant

In this section, we consider the online setting, where new characters are appended to the end of the text \(T\). Given the text \(T[1..i]\) up to position \(i\) with the Lempel-Ziv factorization \(f_1 \cdots f_y = T[1..i]\), we consider computing the set of all distinct squares of \(f_1 \cdots f_{y-2}\), i.e., up to the last two Lempel-Ziv factors. For this setting, we show that we can compute the set of all distinct
values, and reversed text allows us to compute LCE queries in both directions in constant time. That we consider the text string depth is equal to the longest common extension of the lowest common ancestor of two suffix tree leaves with the labels constructed by Weiner’s algorithm. Overall, these take a total of a predecessor data structure to store the out-going suffix link of each node of the suffix tree time. Since Weiner’s algorithm incrementally constructs the suffix tree of a given text online in time. Assume that we have computed the suffix tree of $T[1..i-1]$. The algorithm processes the new character $T[i]$ by (1) taking the suffix links of the current suffix tree, and (2) adding new leaves where a branching occurs. On adding a new leaf with suffix number $i$, we additionally set LPF[i] to the string depth of its parent. By doing so, we can update the LPF values in time linear in the update time of the suffix tree. We build the semi-dynamic RMQ data structure of Fischer [14] (or of [42] if $n$ is known beforehand) on top of LPF. This data structure takes $O(n)$ words and can perform query and appending operations in constant amortized time.

The second suffix tree construction algorithm is a modified version [4] of Weiner’s algorithm [44] that builds the suffix tree in the reversed order of Ukkonen’s algorithm in $O(n t_{nav})$ time. Since Weiner’s algorithm incrementally constructs the suffix tree of a given text from right to left, we can adapt this algorithm to compute the suffix tree of the reversed text online in $O(n t_{nav})$ time.

To get a suffix tree construction time of $O\left(n \min \left(\log^2 \log n / \log \log \log n, \sqrt{\log n / \log \log n}\right)\right)$, we use the predecessor data structure of Beame and Fich [3]. We create a predecessor data structure to store the children of each suffix tree node, such that we get the navigation time $t_{nav} = O\left(\min \left(\log^2 \log n / \log \log \log n, \sqrt{\log n / \log \log n}\right)\right)$ for both suffix trees. We also create a predecessor data structure to store the out-going suffix link of each node of the suffix tree constructed by Weiner’s algorithm. Overall, these take a total of $O(n)$ words of space.

Finally, our last ingredient is a dynamic lowest common ancestor data structure with $O(n)$ words that performs querying and modification operations in constant time [7]. The lowest common ancestor of two suffix tree leaves with the labels $j$ and $k$ is the node whose string depth is equal to the longest common extension of $T[j..i] \leq T[k..i]$. Remember that we consider the text $T$ up to the position $i$, hence $T[j..i]$ is (currently) the $j$-th suffix. Building this data structure on the suffix tree of the text $T$ and on the suffix tree of the reversed text allows us to compute LCE queries in both directions in constant time.

Given the text $T[1..i] = f_1 \cdots f_g$ up to the $i$-th character, the entries of
LPF\([1..|f_1 \cdots f_{y-2}| - 1]\) are fixed (i.e., they will not change when appending new characters) due to the properties of the Lempel-Ziv factorization. We let the semi-dynamic RMQ data structure grow with LPF, but only up to the fixed range of LPF. Similarly, the text positions from 1 up to \(|f_1 \cdots f_{y-2}| - 1\) are represented as leaves in both suffix trees that are fixed, i.e., these leaves will always be leaves representing their respective suffixes. To sum up, our data structures support LCE queries and RMQs on LPF in the range \([1..|f_1 \cdots f_{y-2}| - 1]\) in constant time.

We adapt the algorithm of Section 4.1 by switching the order of the loops (again). The algorithm first fixes a Lempel-Ziv factor \(f_x\) and then searches for squares with a period between one and \(|f_x| + |f_{x+1}|\). Unfortunately, we would need an extra bit vector for each period so that we can track all found leftmost occurrences. Instead, we use the predecessor data structure of [3] storing the found occurrences of squares as pairs of starting positions and lengths. These pairs can be stored in lexicographic order (first sorted by starting position, then by length). The predecessor data structure will contain at most \(\text{occ}\) elements, hence takes \(\mathcal{O}(\text{occ}) = \mathcal{O}(n)\) words of space. An insertion or a search costs us \(\mathcal{O}\left(\min\left(\lg^2 \lg n / \lg \lg \lg n, \sqrt{\lg n / \lg \lg n}\right)\right)\) time.

Let us assume that we have computed the set for \(T[1..i-1]\), and that the Lempel-Ziv factorization of \(T[1..i-1]\) is \(f_1 \cdots f_y\). If appending a new character \(T[i]\) will result in a new factor \(f_{y+1}\), we check for squares of type Lemma 8(1) and Lemma 8(2) at the borders of \(f_{y-1}\). Duplicates are filtered by the predecessor data structure storing all already reported leftmost occurrences. The algorithm outputs only the leftmost occurrences with the aid of LPF, whose entries are fixed up to the last two factors (this is sufficient since we search for the starting position of the leftmost occurrence of a square with type Lemma 8(1) only in \(T[1..|f_1 \cdots f_{y-1}|]\), including right-rotations). In overall, we need \(\mathcal{O}\left((|f_{y-1}| + |f_y|) \min\left(\lg^2 \lg n / \lg \lg \lg n, \sqrt{\lg n / \lg \lg n}\right)\right)\) time.

5 Applications

In this section, we provide two applications of the (offline) variant.

5.1 Decorating the Suffix Tree with All Squares

Gusfield and Stoye described a representation of the set of all distinct squares by a decoration of the suffix tree, like the highlighted nodes (additionally annotated with its respective square) shown in the suffix tree of our running example below.

![Suffix Tree Example](image)

This representation asks for a set of tuples of the form (node, length) such that each square \(T[i..i+\ell-1]\) is represented by a tuple \((v, \ell)\), where \(v\) is the highest node whose string label has \(T[i..i+\ell-1]\) as a (not necessarily proper) prefix. We show that we can compute
Lemma 11. By feeding the algorithm of Phase II with the above constructed lists \( L_i \) containing the leftmost occurrences of the squares starting at the text position \( i \), it will decorate the suffix tree with all distinct squares.

Proof. We adapt the algorithm of Section 4.1 to build the lists \( L_i \). These lists contain the leftmost occurrences of all squares. In the following we show that no square is left out during the bottom-up traversal. Let us take a suffix tree node \( u \) with its children \( v \) and \( w \). Without loss of generality, assume that the smallest label among all leaves contained in the subtree of \( v \) is smaller than the label of every leaf contained in \( w \)'s subtree. For the sake of contradiction, assume that the list of \( w \) contains the occurrence of a square \( (i, \ell) \) at the time when we pass the list of \( v \) to its parent \( u \). The length \( \ell \) is smaller than \( v \)'s string depth, otherwise it would already have been popped off from the list. But since \( v \)'s subtree contains a leaf whose label \( j \) is the smallest among all labels contained in the subtree of \( w \), the square occurs before at \( T[j..j + \ell - 1] = T[i..i + \ell - 1] \), a contradiction to the distinctness.

This concludes the correctness of the modified algorithm. We immediately get:

Theorem 12. Given \( \text{LPF} \), an \( LCE \) data structure on the reversed text, and the suffix tree of \( T \), we can decorate the suffix tree with all squares of the text in \( O(n\text{\LCE}) \) time. Asides from these data structures, we use \((\text{occ} + n) \log n + z \log z + \min(n + o(n), z \log n) + O(\log n)\) bits of additional working space.

Corollary 13. We can compute the suffix tree and decorate it with all squares of the text in \( O(n/\epsilon) \) time using \((3n + \text{occ} + 2n\epsilon) \log n + z \log z + O(n)\) bits, for a constant \( 0 < \epsilon \leq 1 \).

As an application, we consider the common squares problem: Given a set of non-empty strings with a total length \( n \), we want to find all squares that occur in every string in \( O(n) \) time. We solve this problem by first decorating the generalized suffix tree built on all strings with the distinct squares of all strings. Subsequently, we apply the \( O(n) \) time solution of
Hui [25] that annotates each internal suffix tree node $v$ with the number of strings that contain $v$’s string label. This solves our problem since we can simply report all squares corresponding to nodes whose string labels are found in all strings. This also solves the problem asking for the longest common square of all strings in $O(n)$ time, analogously to the longest common substring problem [22].

The last subsection is dedicated to another application of our suffix tree decoration:

5.2 Computing the Tree Topology of the MAST in Linear Time

A modification of the suffix tree is the minimal augmented suffix tree (MAST) [1]. This tree can answer the number of the non-overlapping occurrences of a substring $S$ of $T$ in $O(|S|)$ time. The MAST can be built in $O(n \log n)$ time [5].

In this section, we show how to compute the tree topology of the MAST in linear time. The topology of the MAST differs to the suffix tree topology by the fact that the root of each square is the string label of an MAST node. Our goal is to compute a list storing the information about where to insert the missing nodes. The list stores tuples consisting of a node $v$ and a length $\ell$; we use this information later to create a new node splitting the edge $(u,v)$ into $(u,w)$ and $(w,v)$, where $u$ is the (former) parent of $v$. We will label $(w,v)$ with the last $\ell$ characters and $(u,v)$ with the rest of the characters of the edge label of $(u,v)$.

To this end, we explore the suffix tree with a top-down traversal while locating the roots of the squares in the order of their lengths. To locate the roots of the squares in linear time we use two data structures. The first one is a semi-dynamic lowest marked ancestor data structure [19]. It allows marking a node and querying for the lowest marked ancestor of a node in constant amortized time. We will use it to mark the area in the suffix tree that has already been processed for finding the roots of the squares.

The second data structure is the list of tuples of the form $(node, length)$ computed in Section 5.1, where each tuple $(v, \ell)$ consists of the length $\ell$ of a square $T[i..i+\ell-1]$ and the highest suffix tree node $v$ whose string label has $T[i..i+\ell-1]$ as a (not necessarily proper) prefix. We sort this list, which we now call $L$, with respect to the square lengths with a linear time integer sorting algorithm.

Finally, we explain the algorithm locating the roots of all squares. We successively process all tuples of $L$, starting with the shortest square length. Given a tuple of $L$ containing the node $v$ and the length $\ell$, we want to split an edge on the path from the root to $v$ and insert a new node whose string depth is $\ell/2$. To this end, we compute the lowest marked ancestor $u$ of $v$. If $u$’s string depth is smaller than $\ell/2$, we mark all descendants of $u$ whose string depths are smaller than $\ell/2$, and additionally the children of those nodes (this can be done by a DFS or a BFS). If we query for the lowest marked ancestor of $u$ again, we get an ancestor $w$ whose string depth is at least $\ell/2$, and whose parent has a string depth less than $\ell/2$. We report $w$ and the subtraction of $\ell/2$ from $w$’s string depth (if $\ell/2$ is equal to the string depth
of $w$, then $w$’s string label is equal to the root of $v$’s string label, i.e., we do not have to report it).

▶ **Theorem 14.** We can compute the tree topology of the MAST in linear time using linear number of words.

**Proof.** By using the semi-dynamic lowest marked ancestor data structure, we visit a node as many times as we have to insert nodes on the edge to its parent, plus one. This gives $O(n + 2\text{occ}) = O(n)$ time.

**Open Problems.** It is left open to compute the number of the non-overlapping occurrences of the string labels of the MAST nodes in linear time. Since RMQ data structures are practically slow, we wonder whether we can avoid the use of any RMQ without losing linear running time. The current bottleneck of the online algorithm is the predecessor data structure in terms of the running time. Future integer dictionary data structures can improve the overall performance of this algorithm.

**Acknowledgements.** We thank Thomas Schwentick for the question whether we can run our algorithm online, for which we provided a solution in Section 4.4.

The text \( T = a \text{b} \text{a} \text{b} \text{a} \text{a} \text{b} \text{a} \text{b} \text{a} \text{b} \text{a} \$ \) = \( f_1 \cdots f_6 \) is factorized in six Lempel-Ziv factors. We call \( T[1+|f_1 \cdots f_{i-1}|] \) (first position of the \( i \)-th factor) and \( T[1+|f_i \cdots f_{i}|] \) (position after the \( i \)-th factor) the left border and the right border of \( f_i \), respectively. The idea of the algorithm is to check the presence of a square at a factor border and at an offset value \( q \) of the border with LCE queries. \( q \) is either the addition of \( p \) to the left border, or the subtraction of \( p \) from the right border (see Figure 1).

The algorithm finds the leftmost occurrences of all squares in the order (first) of their lengths and (second) of their starting positions. We start with the period \( p = 1 \) and try to detect squares at each Lempel-Ziv factor border. To this end, we create a bit vector \( B \) marking all found squares with period \( p = 1 \). A square of this period is found at the right border of \( f_3 \). It is of type Lemma 8(1), since its starting position is in \( f_3 \). To find it, we take the right border \( b = 6 \) of \( f_3 \), and the position \( q := b - p = 5 \). We perform an LCE query at \( b \) and \( q \) in the forward and backward direction. Only the forward query returns the non-zero value of one. But this is sufficient to find the square \( \text{aa} \) of period one. Its LPF value is smaller than \( 2p = 2 \), so it is the leftmost occurrence. It is not yet marked in \( B \), thus we have not yet reported it. Right-rotations are not necessary for period 1. Having found all squares with period 1, we clear \( B \).
Next, we search for squares with period 2. We find a square of type Lemma 8(2) at the left border \( b = 2 \) of \( f_2 \). To this end, we perform an LCE query starting from \( b \) and \( q := b + p = 4 \) in both directions. Both LCE queries show that \( T[1..5] \) is a repetition with period \( p = 2 \). Thus we know that \( T[1..4] \) is a square. It is not yet marked in \( B \), and has an LPF value smaller than \( 2p = 4 \), i.e., it is a not yet reported leftmost occurrence. On finding a leftmost occurrence of a square, we right-rotate it, and report all right-rotations whose LPF values are below \( 2p \). This is the case for \( T[2..5] \), which is the leftmost occurrence of the square \textit{baba}.

After some unsuccessful checks at the next factor borders, we come to factor \( f_5 \) and search for a square of type Lemma 8(2). Two LCE queries in both directions at the left border \( b = 8 \) of \( f_5 \) and \( q := b + p = 10 \) reveal that \( T[7..11] \) is a repetition of period 2. The substring \( T[7..10] \) is a square, but its LPF value is \( 5(\geq 2p) \), i.e., we have already reported this square. Although we have already reported it, some right-rotation of it might not have been reported yet (see Section 4.2 for an example). This time, all right-rotations (i.e., \( T[8..12] \)) have an LPF value \( \geq 2p \), i.e., there is no leftmost occurrence of a square of period 2 found by right-rotations. In overall, we have found and reported the leftmost occurrences of all squares once.

C Proofs

Proof of Theorem 12

\textbf{Proof.} We need \((\text{occ} + n)\lg n\) bits for storing the lists \( L_i \) (\( \text{occ} \lg n \) bits for storing the lengths of all squares in an integer array, and \( n \lg n \) bits for the pointers to the first element of each list). The array \( Z \) uses \( z \lg z \) bits. The Lempel-Ziv factors are represented as in Corollary 1. The time \( t_{\text{LCE}} \) is the maximum time of the LCE data structure and the suffix tree for answering an LCE query.

\textbf{Proof of Theorem 13}

\textbf{Proof.} We use Theorem 6 to store \( \text{SA}, \text{ISA}, \text{LCP} \), and \( \text{LPF} \) in \((1 + \epsilon) \lg n + O(n)\) bits. Subsequently, we build an RMQ data structure on \( \text{LCP} \) such that LCE queries can be
answered in constant time. We additionally need the suffix array, its inverse, and the LCP array (with an RMQ data structure) of the reversed text to answer LCE queries on the reversed text. Finally, we endow LPF with an RMQ data structure for the right-rotations. An LCE query on the text can be answered by the string depth of a lowest common ancestor in the suffix tree in constant time.

35. right-rotate(s, p)
Abstract

Palindromic length of a string is the minimum number of palindromes whose concatenation is equal to this string. The problem of finding the palindromic length drew some attention, and a few $O(n \log n)$ time online algorithms were recently designed for it. In this paper we present the first linear time online algorithm for this problem.

1 Introduction

Algorithmic and combinatorial problems involving palindromes attracted the attention of researchers since the first days of stringology. Recall that a string $w = a_0 a_1 \cdots a_{n-1}$ is a palindrome if it is equal to the string $\bar{w} = a_{n-1} \cdots a_1 a_0$. The early works [4, 6, 8, 11] considered palindromes as structures that might provide examples of (context-free) languages that are impossible to recognize in linear time, thus provably restricting the computational power of some models (RAM, in particular). Subsequently, it was shown that many of such languages are, in fact, linear recognizable. Recently it was proved [7] that the language $P_k$, where $P$ is the set of all palindromes on a given alphabet, is recognizable online in $O(kn)$ time, where $n$ is the length of the input string. Roughly at the same time, a closely related notion of palindromic length of a string was introduced: this is the minimal number $k$ such that the string belongs to $P^k$. In 2014–2015 three different algorithms that compute the palindromic length of a string of length $n$ in $O(n \log n)$ time were presented in [3, 5, 10] (however, they all are based on similar principles). In this paper we present the first linear algorithm computing the palindromic length. Moreover, our algorithm is online, i.e., it reads the input string sequentially from left to right and computes the palindromic length for each prefix after reading the rightmost letter of that prefix. Thus, we prove the following theorem.

Theorem 1. Palindromic length of a string is computable online in linear time.

The implementation of our algorithm and tests for it can be found in [9]. Due to a large constant under the big-O, it is slower in practice (for 32/64 bit machine words) than the existing $O(n \log n)$ solutions; the fastest algorithm is the one of [10].
23.2 Palindromic Length in Linear Time

The paper is organized as follows. Section 2 contains a high-level description of the algorithm: it starts with a naive $O(n^2)$ algorithm, then improves the time to $O(n \log n)$, and, finally, describes on a high level a modified $O(n)$-time version of the $O(n \log n)$ algorithm. In Section 3 we discuss the main components of the linear algorithm in details.

1.1 Preliminaries

Let $w$ be a string of length $n = |w|$. We write $w[i]$ for the $i$th letter of $w$ ($i = 0, \ldots, n-1$) and $w[i..j]$ for $w[i]w[i+1] \cdots w[j]$. A string $u$ is a substring of $w$ if $u = w[i..j]$ for some $i, j$. Such pair $(i, j)$ is not necessarily unique; $i$ specifies an occurrence of $u$ at position $i$. A substring $w[0..j]$ (resp., $w[i..n-1]$) is a prefix (resp. suffix) of $w$. The empty string is denoted by $\varepsilon$. For any $i, j$, $[i..j]$ denotes the set $\{k \in \mathbb{Z}: i \leq k \leq j\}$; let $(i..j) = [i..j] \setminus \{i\}$, $[i..j) = [i..j] \setminus \{j\}$, $(i..j) = [i..j] \cap (i..j)$. Our notation for arrays is the same as for strings.

A substring (resp. suffix, prefix) that is a palindromic is called a subpalindrome (resp. suffix-palindrome, prefix-palindrome). If $w[i..j]$ is a subpalindrome of $w$, then the number $(j+1)/2$ is the center of $w[i..j]$ and the number $(j-i+1)/2$ is the radius of $w[i..j]$. The following remarkable property of palindromic lengths is crucial for our algorithm.

▶ Lemma 2 (see [10, Lemma 11]). Denote by $\ell_0, \ell_1, \ldots, \ell_{n-1}$, resp., the palindromic lengths of the prefixes $w[0..0], w[0..1], \ldots, w[0..n-1]$ of a string $w$. Then, for any $i \in (0..n)$, $|\ell_i - \ell_{i-1}| \leq 1$.

An integer $p$ is a period of $w$ if $w[i] = w[i+p]$ for any $i \in (0..n-p)$. As the previous results [3, 5, 10], our approach relies on a number of periodic properties of palindromes.

▶ Lemma 3 (see [7, Lemmas 2, 3]). For any palindromic $w$ and any $p \in (0..|w|)$, the following conditions are equivalent: (1) $p$ is a period of $w$, (2) there are palindromes $u, v$ such that $|uv| = p$ and $w = (uv)^k u$ for some $k \geq 1$, (3) $w[p..|w|-1]$ is a palindromic.

▶ Lemma 4 (see [7, Lemma 7]). Suppose that $w = (uv)^k u$ for $k \geq 1$ and for palindromes $u$ and $v$ such that $|uv|$ is the minimal period of $w$; then, the center of any subpalindrome $x$ of $w$ such that $|x| \geq |w| - 1$ coincides with the center of some $u$ or $v$ from the decomposition.

Henceforth, let $s$ denote the input string of length $n$. We assume that the algorithm works in the unit-cost word-RAM model with $\Theta(\log n)$-bit machine words (an assumption justified in, e.g., [2]) and standard operations like in the C programming language.

2 High-Level Description of the Algorithm

Our aim is to maintain an array $\text{ans}[0..n-1]$ in which each element $\text{ans}[i]$ is the palindromic length of $s[0..i]$. We always assume $n$ to be the length of the string $s$ processed so far (i.e., $s = s[0..n-1]$). Processing the next letter $s[n]$, we compute $\text{ans}[n]$ and then increment $n$.

2.1 Naïve approach

An easy quadratic-time approach is to maintain the list of all non-empty suffix-palindromes $u_1, \ldots, u_k$ of the string $s$ and calculate $\text{ans}[n] = 1 + \min_{i \in [1..k]} \text{ans}[n-|u_i|]$. The list can be updated in linear time: the suffix-palindromes of $w$ have the form $aua$, where $u$ is a suffix palindrome of $w$, plus the palindrome $a$ and, optionally, $aa$. As a first speedup to this basic approach, we utilize the (palindromic) iterator, introduced in [7]; this data structure contains a string $s$ and supports the following operations:
1. \textit{add}(a) appends the letter \(a\) to the end of \(s\);
2. \textit{maxPal}\ returns the center of the longest suffix-palindrome of \(s\);
3. \textit{rad}(x) returns the radius of the longest subpalindrome of \(s\) with the center \(x\);
4. \textit{nextPal}(x) returns the center of the longest proper suffix-palindrome of the suffix-
    palindrome of \(s\) with the center \(x\); undefined if \(x\) is not the center of a suffix-palindrome.

The iterator can be implemented so that all its operations work in \(O(1)\) time (amortized,
for \textit{add})\cite{7, Prop. 1}. The same time bound applies to computing length of the longest
subpalindrome centered at \(x\): \(\text{len}(x) = 2 \cdot \text{rad}(x) + |x| - \lfloor x - \frac{1}{2} \rfloor\). Still, the iterator alone
cannot lower the asymptotic time of the naive algorithm; its improved version looks as follows:

\begin{enumerate}
  \item \textit{add}(s[n]); \(\text{ans}[n] \leftarrow +\infty\)
  \item \textbf{for} \((x \leftarrow \text{maxPal};\ x \neq n + \frac{1}{2};\ x \leftarrow \text{nextPal}(x))\) \textbf{do} \(\text{ans}[n] \leftarrow \min\{\text{ans}[n], 1 + \text{ans}[n - \text{len}(x)]\}\)
\end{enumerate}

2.2 Algorithm working in \(O(n \log n)\) time

All subquadratic algorithms for palindromic length heavily use grouping of suffix-palindromes
into series. Let \(u_1, \ldots, u_k\) be all non-empty suffix-palindromes of a string \(s\) in the order of
decreasing length. Since \(u_j\) is a suffix of \(u_i\) for any \(i < j\), any period of \(u_i\) is a period of
\(u_j\); hence the sequence of minimal periods of \(u_1, \ldots, u_k\) is non-increasing. The groups of
suffix-palindromes with the same minimal period are series of palindromes (of \(s\)):

\[
\begin{align*}
  u_1, & u_{i_2}, u_{i_3+1}, \ldots, u_{i_2}, \ldots, u_{i_{k-1}+1}, \ldots, u_k.
\end{align*}
\]

We refer to the longest and the shortest palindrome in a series as its \textit{head} and \textit{baby} respectively
(they coincide in the case of a 1-element series); we enumerate the elements of a series from the
head to the baby. Given an integer \(p\), the \textit{p-series} is the series with period \(p\). A very
useful observation\cite{3, 5, 7} is that the length of a head is multiplicatively smaller than the
length of the baby from the previous series, and thus every string of length \(n\) has \(O(\log n)\)
series. (As it was shown in \cite{3}, strings with \(\Omega(\log n)\) series for \(\Omega(n)\) prefixes do exist.)

The idea of the \(O(n \log n)\) solution is to use the dynamic programming rule \(\text{ans}[n] =
1 + \min_{u \in U} \min_{v \in V} \text{ans}[n - |u|]\), where \(U\) runs through the series of \(s\), and compute the internal
minimum in \(O(1)\) time using precalculations based on the structure of series. The structure
of any series is described in the following lemma, which is easily implied by Lemmas 3, 4.

\begin{lemma}
For a string \(s\) and \(p \geq 1\), let \(U\) be a \(p\)-series of palindromes. There exist \(k \geq 1\)
and unique palindromes \(u, v\) with \(|vw| = p, v \neq \varepsilon\) such that one of three conditions hold:
\begin{itemize}
  \item \(U = \{(uv)^{k+1}u, (uv)ku, \ldots, (uv)^2u\}\) and the next series begins with \(wu\),
  \item \(U = \{(uv)^ku, (uv)^{k-1}u, \ldots, wu\}\) and the next series begins with \(u\),
  \item \(U = \{v^k, v^{k-1}, \ldots, v\}\), \(p = 1, |v| = 1, u = \varepsilon\), and \(U\) is the last series for \(s\).
\end{itemize}
\end{lemma}

Let \(U\) be a \(p\)-series for \(s[0..n]\) with \(k > 1\) palindromes (w.l.o.g., \(U = \{(uv)^ku, \ldots, wu\}\)).
Updating \(\text{ans}[n]\) using this series, we compute \(m = \min\{\text{ans}[n - kp - |u|], \ldots, \text{ans}[n - p - |u|]\}\).
Now note that \(s[0..n]\) ends with \((uv)^k u\) but not with \((uv)^{k+1} u\); otherwise, the latter
string would belong to \(U\). Then \(s[0..n-p]\) ends with \((uv)^{k-1} u\) but not with \((uv)^ku\) and
thus has the \(p\)-series \(U' = \{(uv)^{k-1}u, \ldots, wu\}\). Thus, at that iteration we computed
\(m' = \min\{\text{ans}[n - kp - |u|], \ldots, \text{ans}[n - 2p - |u|]\}\) for updating \(\text{ans}[n-p]\). If we save \(m'\) into
an auxiliary array, then \(m = \min\{m', \text{ans}[n - p - |u|]\}\) is computable in constant time, as
required. Let us implement this construction using the iterator.

We start an iteration calling \(\text{add}(s[n])\). Let \(x\) be the center of a suffix-palindrome \(u\). By
Lemma 3, the minimal period \(p\) of \(u\) equals \(\text{len}(x) - \text{len}(\text{nextPal}(x))\). Let \(\text{cntr}(d)\) denote
the center of the length $d$ suffix-palindrome of $s[0..n]$ (i.e., $\text{cntr}(d) = n - (d - 1)/2$). Let $x' = \text{cntr}(p + (\text{len}(x) \mod p))$. By Lemma 5, $x'$ is the center either of the baby of the $p$-series or of the head of the next series, depending on the period $\text{len}(x') - \text{len}(\text{nextPal}(x'))$ of this suffix-palindrome. All these computations take $O(1)$ amortized time using the iterator.

Our algorithm maintains an array $\text{left}[1..n]$: for $p \in [1..n]$, if there is a $p$-series, then $s[\text{left}[p]+1..n]$ is the longest suffix (which is not necessarily a palindrome) of $s[0..n]$ with period $p$; otherwise, $\text{left}[p]$ is undefined. E.g., if $s[0..n] = \cdots \cdot aabaaba$ and $p = 3$, then the mentioned suffix is $s[n-6..n] = aabaaba$ and $\text{left}[3] = n - 7$. Computing $\text{left}[p]$ in $O(1)$ time is done as follows. Let $w = (uv)^k u$ be the head of the $p$-series (see Lemma 5), $x$ be the center of $w$, and $z(w)^k u$ be the longest suffix of $s[0..n]$ with period $p$ (in our example, $u = \varepsilon$, $v = aba$, $x = n - 5/2$, $z = a$). Then $z$ is a proper suffix of $w$. Hence $\text{len}(x_1) = 2|z| + |u|$, where $x_1$ is the center of the prefix-palindrome $u$ of $w$ (in the example, $x_1 = n - 11/2$, $\text{len}(x_1) = |aa|$).

Note that $|u| = \text{len}(x)$ mod $p$ and $x_1 = 2x - x_2$, where $x_2 = \text{cntr}(\text{len}(x) \mod p)$ is the center of the suffix $u$ of $w$. Thus, $|z|$ and $\text{left}[p] = n - \text{len}(x) - |z|$ are computed in $O(1)$ time.

All precalculated minimums are stored in an array $\text{pre}[1..n]$, where each $\text{pre}[p]$ is, in turn, an array $\text{pre}[p][0..p-1]$ (we discuss in the next subsection why only $O(n)$ of possible $O(n^2)$ elements of $\text{pre}$ are actually stored). For each $j$ such that $n - j > \text{left}[p]$, the string $s[0..n-j]$ has a suffix-palindrome with period $p$ and thus can have a $p$-series; the array $\text{pre}[p][0..p-1]$ contains the precalculations made for all these series. Formally,

$$\text{pre}[p][i] = \min\{\text{ans}[t];$$

$$(t - \text{left}[p]) \mod p = i \text{ and } s[t+1..n] \text{ has a prefix-palindrome of minimal period } p\};$$

$\text{pre}[p][i]$ is undefined if there is no such $t$ (i.e., no $p$-series for the corresponding string). So if $u_1, \ldots, u_k$ is a $p$-series for $s[0..n]$, then $\text{pre}[p][n-|u_1| - \text{left}[p]] = \min\{\text{ans}[n-|u_i|]; \ i \in [1..k]\}$. Hence, given a new letter $s[n]$, we compute $\text{ans}[n]$ as follows:

1: $\text{add}(s[n]); \ \text{ans}[n] \leftarrow +\infty;
$  
2: $\text{for} \ (x \leftarrow \text{maxPal}; \ x \neq n + \frac{1}{2}; \ x \leftarrow \text{nextPal}(\text{cntr}(d))) \ \text{do} \quad \triangleright \text{goes to next head each time}$
3: $\quad p \leftarrow \text{len}(x) - \text{len}(\text{nextPal}(x)); \quad \triangleright \text{min. period of the suf.-pal. centered at } x$
4: $\quad d \leftarrow p + (\text{len}(x) \mod p); \quad \triangleright \text{length of the baby in the } p$-series
5: $\quad \text{if } \text{len}(\text{cntr}(d)) - \text{len}(\text{nextPal}(\text{cntr}(d))) \neq p \ \text{then} \ d \leftarrow d + p; \quad \triangleright \text{corrected length}$
6: $\quad \text{compute left}[p]; \quad \triangleright \text{in } O(1) \text{ time, see above}$
7: $\quad \text{if } \text{len}(x) = d \ \text{then} \ \text{pre}[p][n-\text{len}(x) - \text{left}[p]] \leftarrow \text{ans}[n-d];$
8: $\quad \text{pre}[p][n-\text{len}(x) - \text{left}[p]] \leftarrow \min\{\text{pre}[p][n-\text{len}(x) - \text{left}[p]], \text{ans}[n-d]\};$
9: $\quad \text{ans}[n] \leftarrow \min\{\text{ans}[n], 1 + \text{pre}[p][n-\text{len}(x) - \text{left}[p]]\};$

Let $u_1, \ldots, u_k$ be a $p$-series, $i = n-|u_1| - \text{left}[p]$. If $k = 1$, there was no $p$-series $p$ iterations ago, so we set the undefined value $\text{pre}[p][i]$ to $\text{ans}[n-|u_k|]$ in line 7. Otherwise, by the definition of $\text{pre}$, we have $\text{pre}[p][i] = \min\{\text{ans}[n-|u_1|], \ldots, \text{ans}[n-|u_k-1|]\}$. We update this value using $\text{ans}[n-|u_k|]$ in line 8. So $\text{pre}$ is correctly maintained, and the above algorithm computes the array $\text{ans}$ in $O(n \log n)$ time due to logarithmic number of series.

### 2.3 Sketch of the Linear Algorithm

The idea of the linear solution is to perform the above log-time processing of all series of the current string not $n$ times, but only $O\left(\frac{n}{\log n}\right)$ times during the run of the algorithm. (However, we are able to make $\Theta(n)$ calls to the iterator.) To achieve this, during the processing of a series we replace each computation of the minimum $\text{ans}[n] \leftarrow \min\{\text{ans}[n], 1 + z\}$, for a precomputed value $z$ from $\text{pre}$, with the simultaneous computation (“prediction”) for the range of values $\text{ans}[n..n+b]$, where $b = \lfloor \frac{\log n}{8}\rfloor$: we compute in advance $\text{ans}[j] \leftarrow \min\{\text{ans}[j], 1 + z_j\}$
for all $j \in [n..n+b]$ and corresponding precomputed $z_j$ from pre. It is proved below that the arrays ans and pre can be organized so that, after a linear time preprocessing, such range operations on $O(b)$ elements of ans will take $O(1)$ time (this type of bit compression techniques is referred to as the four Russians’ trick [1]).

Let us extend $s[0..n-1]$ with $s[n] = a$. We say that a suffix-palindrome $u$ of $s[0..n-1]$, centered at $x$, survives if $s[0..n]$ has the suffix $aua$ (i.e., $x$ remains the center of a suffix-palindrome), and dies otherwise. We say that an extension of $s[0..n-1]$ by $s[n]$ is predictable if it retains maxPal, i.e., if the longest suffix-palindrome survives. From maxPal it can be calculated which of the other suffix-palindromes survive. If a suffix-palindrome of $s$ centered at $x$ survives $d \geq 0$ consecutive predictable extensions but dies after the $(d+1)$th such extension (or the $(d+1)$th predictable extension is not possible), we write $\text{live}(x) = d$. We have $\text{live}(\text{maxPal}) = n - \text{len}(\text{maxPal})$ and $\text{live}(x) = \text{rad}(\text{refl}(x)) - \text{rad}(x)$ for $x \neq \text{maxPal};$ here refl($x$) = 2 · maxPal − $x$ is the position symmetric to $x$ w.r.t. maxPal. (See Fig. 1 for clarification; e.g., in Fig. 1 $\text{live}(x) = 2$ and $\text{live}(\text{maxPal}) = 6$.)

Suppose that $\text{ans}[n+j] = +\infty$ for $j \in [0..b]$. Having performed $\text{add}(s[n])$, we get access to the suffix-palindromes of $s[0..n]$. If, for the center $x$ of each such palindrome, we perform
\[
\text{ans}[n+j] \leftarrow \min\{\text{ans}[n+j], 1 + \text{ans}[n-\text{len}(x)-j]\} \text{ for all } j \in [0..\min\{b, \text{live}(x)\}],
\]
then we accumulate all information we can obtain from these palindromes during the next $b$ predictable extensions. Thus we get an approximation of $\text{ans}[n..n+b]$, which will later be updated using suffix-palindromes with the centers $x \geq n+\frac{1}{2}$. One phase of our algorithm is roughly as follows:

1. append $s[n]$ to the iterator, update precalculations, and “predict” $\text{ans}[n..n+b]$ with the assignments $\text{ans}[n+j] \leftarrow \min\{\text{ans}[n+j], 1 + \text{ans}[n-\text{len}(x)-j]\}$ for all $j \in [0..\min\{b, \text{live}(x)\}]$;
2. append subsequent letters, each time updating the predictions with either one or two new palindromes (after processing $\text{ans}[n+j]$), $\text{ans}[n..n+j]$ contains correct values;
3. stop after $b$ iterations or at the moment when an unpredicted letter is encountered;
4. discard unused predictions and start a new phase with the first unpredicted letter.

For arrays $\alpha, \beta$ and numbers $i, j, k \geq 0$, denote by $\alpha[i..i+k] \leftrightarrow \min\{\alpha[i+k], \beta[j..j+k]\}$ the sequence of assignments $\alpha[i+k] \leftarrow \min\{\alpha[i+k], \beta[j..j+k]\}$ for all $k \in [0..\ell]$. Let $\text{inrev}(i, j)$ be the function returning an array $a[0..j-i]$ such that $a[k] = 1 + \text{ans}[j-k]$ for $k \in [0..j-i]$ (‘‘increment & reverse’’). The predictions are made by the function $\text{predict}$ that uses precalculations stored in pre to perform in a fast way the assignments $\text{ans}[n..n+c] \leftarrow \text{inrev}(\text{ans}[n-\text{len}(x)-c, n-\text{len}(x)])$, where $c = \min\{b, \text{live}(x)\}$, for all centers of suffix-palindromes. (Hence predict computes the value $\text{ans}[n]$ correctly even if $c = 0$ for some $x$.) Let $\text{precalc}$ be a function that updates (possibly once in several iterations) the array pre to the actual state. The implementations of predict and precalc are discussed in Section 3. Our algorithm is as follows:

1: for $n \leftarrow 0, \ell \leftarrow 0$; not(end_of_input); $n \leftarrow n + 1$ do
2: if $n = \text{end}$ or $\text{len}(\text{maxPal}) = n$ or $s[n] \neq s[n-\text{len}(\text{maxPal})-1]$ then \hspace{1cm} \triangleright new phase
3: \hspace{1cm} $\text{add}(s[n])$; $\text{precalc}$; $\text{predict}$; $\text{end} \leftarrow n + b$
4: else $\text{add}(s[n])$ \hspace{1cm} \triangleright old phase continues, $s[n]$ is predictable
5: \hspace{1cm} $c \leftarrow \min\{b, \text{live}(n)\}$; $\text{ans}[n..n+c] \leftarrow \text{inrev}(n-1-c, n-1)$
6: if $s[n] = s[n-1]$ then $c \leftarrow \min\{b, \text{live}(n-\frac{1}{2})\}$; $\text{ans}[n..n+c] \leftarrow \text{inrev}(n-2-c, n-2)$

**Figure 1** Predictable extensions.
This algorithm computes the same values \( \text{ans}[n] \) as the \( O(n \log n) \) algorithm above, because finally all suffix-palindromes of \( s[0..n] \) are used. So, the algorithm is correct.

Let \( t \) be the number of series in the current string \( s[0..n] \) and \( q \) is the time required to perform all the calls \( \text{add}(s[n]), \text{add}(s[n-1]), \ldots, \text{add}(s[n'+1]) \), where \( s[0..n'] \) is the string for which \( \text{precalc} \) was called last time. Below we show that \( \text{predict} \) and \( \text{precalc} \) work in \( O(t) \) and \( O(t + q) \) time respectively, and the array \( \text{ans} \) can be organized so that the range operations in lines 5–6 can be performed in \( O(1) \) time using the four Russians’ trick. Let us estimate the running time of the algorithm under these assumptions.

During predictable extensions, line 3 is reached iff \( n = \text{end} \), i.e., at most \( O(n) \) times. Since \( \text{add} \) works in \( O(1) \) amortized time (see [7, Prop. 1]), the sum of all \( q \)'s in the running time of \( \text{precalc} \) is \( O(n) \). Since \( O(t) = O(\log n) \), all predictable extensions take \( O(n + \frac{n}{2} \log n) = O(n) \) overall time. To estimate the running time of unpredictable extensions, consider the value \( \gamma_i = \text{live}[\text{maxPal}] = i - \text{len}(\text{maxPal}) \) after processing \( s[0..i] \). If \( s[i+1] \) is predictable, one has \( \gamma_{i+1} = (i + 1) - (\text{len}(\text{maxPal}) + 2) = \gamma_i - 1 \). If \( s[i+1] \) is unpredictable, \( \gamma_{i+1} \geq (i + 1) - (\text{len}(\text{nextPal}(\text{maxPal})) + 2) \); by Lemma 5, \( \gamma_{i+1} - \gamma_i \geq p - 1 \), where \( p \) is the minimal period of the longest suffix-palindrome of \( s[0..i] \). By Lemmas 4 and 5, the length of the longest suffix-palindrome whose minimal period differs from \( p \) is less than \( 2p \). Therefore, \( \text{predict} \) and \( \text{precalc} \) take \( O(p + q) \) time during this unpredictable extension (actually, \( O(\log p + q) \)). Since \( \gamma_n - \gamma_1 < n \), the sum of the working times of all calls to \( \text{predict} \) and \( \text{precalc} \) is \( O(n) \).

### 2.4 Organization of the arrays \( \text{ans} \) and \( \text{pre} \)

Informally, the four Russians’ trick allows us to compute any operation on structures of size \( \leq \log n \) bits in \( O(1) \) time using a precomputed table of size \( O(n^2 \log^O(1) n) \) bits. For example, let a \([\log_2 n]\)-bit integer \( x \) encode a sequence \( x_1, \ldots, x_{\lceil \log_2 n \rceil} \) so that \( x_j = 1 - ((x_{j+1} \lceil 2^{j+1} \rceil) \mod 4) \), i.e., \((2j-1)\)th and \((2j-2)\)th bits of \( x \) encode \( x_j \). We can compute, for \( j \in [1..\log n/4] \), the sum \( x_1 + \cdots + x_j \) in \( O(1) \) time using a table \( T[0..\lfloor \sqrt{n} \rfloor][1..\lceil \log n/4 \rceil] \) such that \( T[x][j] = x_1 + \cdots + x_j \) for any \( x \in [0..2^{\log n/2}] = [0..\sqrt{n}] \) and \( j \in [1..\log n/4] \). The table \( T \) can be precomputed in \( O(\sqrt{n} \log^O(1) n) \) time.

In our case, we split \( \text{ans} \) into blocks of length \( b \). By Lemma 2, adjacent elements of \( \text{ans} \) differ by at most one. This allows us to encode each block \( \text{ans}[ib+1..(i+1)b] \) as the number \( \text{ans}[ib+1] \) and the sequence \( x_1, x_2, \ldots, x_b \) such that \( x_j \in \{-1, 0, 1\} \) and \( \text{ans}[ib+j] = \text{ans}[ib+1] + x_1 + \cdots + x_j \) for any \( j \in [1..b] \). This sequence \( x_1, x_2, \ldots, x_b \) is encoded in a 2b-bit integer exactly as in the example above (note that \( 2b \leq \lceil \log_2 n \rceil \)). Using a precomputed table of size \( O(\sqrt{nb}) \), we can extract any element \( \text{ans}[j] \) in \( O(1) \) time. It is shown in Sect. 3 that arrays in \( \text{pre} \) can be encoded in a similar way (with some additional complications).

Applying a similar trick, one can perform many other operations. Let \( c[0..\ell] \) be an array of integers such that \( \ell \in [0..b] \), \( |c[i-1] - c[i]| \leq 1 \), and \( c \) is encoded, like a block of \( \text{ans} \), by \( c[0] \) and a 2b-bit integer. Let us show how to perform in \( O(1) \) time the operation \( \text{ans}[n+n+\ell] \overset{\text{min}}{\leftarrow} c[0..\ell] \) as in lines 5–6 of the algorithm (similar operations are also performed in \( \text{predict} \)). We first check whether \( c[0] > \text{ans}[n] + 2\ell \); if so, then \( \text{ans} \) remains unchanged. It is guaranteed by the algorithm that \( c[0] \geq \text{ans}[n-1] - 1 \). Then, we concatenate bit representations of all required components: the (at most) two blocks \( \text{ans}[ib+1..(i+1)b] \) and \( \text{ans}[(i+1)b+1..(i+2)b] \) encoding the subarray \( \text{ans}[n+n+\ell] \) are stored as two 2b-bit sequences (encoding the differences \( \text{ans}[i+1] - \text{ans}[i] \) for \( i \in [ib+2..(i+2)b] \) as above), \( c[0..\ell] \) is also stored as a 2b-bit sequence, the offset \( (n-ib) \) and the difference \( c[0] - \text{ans}[n-1] \) are stored as \( O(\log b) \)-bit integers; \( 6b + O(\log b) \) bits in total. We precompute a table \( T \) that, for a given
combined bit representation, stores two 2k-bit sequences encoding two blocks that represent
the resulting modified ans[n..n+\ell] array. It should be noted that the information provided
in the given representation suffices to compute the result and, since the resulting array ans
satisfies Lemma 2, we may put ans[n+\ell+j] = \min\{ans[n+\ell+j], ans[n+\ell] + j\} for j ≥ 1 so
that the structure of the last block is preserved. Since 6b ≤ \frac{3}{2} \log n, the size of the table T
is O(b^2 2^{6b+O(\log b)}) = O(n^{3/4} \log^k n) for some k = O(1). Obviously, T can be precomputed
in O(n^{3/4} \log^k + O(1)n) time. Analogously, we precompute tables that allow us to calculate
inc\(v\)(i, j) in O(1) time if j − i ≤ b; the resulting array of inc\(v\) is encoded, like the array
c, by the first element and a 2k-bit integer. Thus, all range operations in lines 5–6 of the
algorithm can be performed in O(1) time.

We use a number of different range operations on the arrays ans and pre in Section 3 but
all of them are similar to the discussed ones, so we omit detailed descriptions.

3 Implementation of the Main Functions

Now it remains to describe the functions predict and pre\(c\)alc and prove their time complexity.

3.1 Function predict

At the beginning, the function predict sets ans[n+j] ← ans[n−1]+j+1 for j ∈ [0..b]. By
Lemma 2, the assigned values are upper bounds for the elements of ans[n..n+b]. The
assignments are performed in O(1) time using range operations. Then predict processes each
of the t series; let us describe precisely how we process a p-series u_1, \ldots, u_k.

Let u, \(\varepsilon\) be the palindromes described in Lemma 5, x_i be the center of u_i for i ∈ [1..k]. If
\(\text{len}(x_i) < n − \text{left}[p]\) (i.e., either i > 1 or i = 1 and u_1 is not the longest suffix of s with period
p), then x_i will remain the center of a new suffix-palindrome after the appending of s[n] iff
s[n] = s[n−p] = v[0]. In this case, the period p “extends” and x_i remains the center of a
suffix-palindrome with the minimal period p. In the remaining case \(\text{len}(x_1) = n − \text{left}[p]\) (u_1
is the longest suffix with period p) x_1 will remain the center of a suffix-palindrome iff s[n] =
\(s[\text{left}[p]]\); the period p breaks and the palindrome s[n]u_1s[n] will belong to a different series.

Suppose that d upcoming predictable extensions extend the period p of the suffix
s[\text{left}[p]+1..n−1] and the (d+1)st predictable extension breaks this period. It follows from
the previous paragraph that the only suffix-palindrome u_i that can survive the (d+1)st
extension (in other words, for which live(x_i) > d) must have length n − \text{left}[p] − d (see Fig. 2).
So if d is known, we check whether \(x = \text{cntr}(n−\text{left}[p]−d)\) is the center of a suffix-palindrome
(i.e., cn\(v\)(\text{len}(x)) = x) and, if so, we compute ans[n..n+c] ← min\(\{\)inc\(v\)(n−\text{len}(x)−c, n−\text{len}(x))\),
where c = min\{b, \text{live}(x)\}, in O(1) time using range operations.

Now it remains to find d and change ans[n..n+\min\{b, d\}] taking u_1, \ldots, u_k into account.
Since predictable extensions append the letters s[n−\text{len}(\text{maxPal})], s[n−\text{len}(\text{maxPal})−1], \ldots
to the right of s, we can approximately find d looking at the string \(s[0..n−\text{len}(\text{maxPal})−1]\).
Put \(d' = \min\{\text{live}(\text{cntr}[u_1])\}, \text{live}(\text{cntr}[wux])\}\) (see Fig. 2). Let us show that we can use \(d'\)
instead of \(d\). If \(d' < n − \text{left}[p] − |wux|\), then the longest suffix-palindrome is preceded by
the reversed prefix of \((wux)^\infty\) of length \(d'\). In turn, this prefix either is preceded by a letter
that breaks the period p of this prefix (the letter e in Fig. 2) or is a prefix of the whole
string. In either case, \(d'' = d\). If \(d'' ≥ n − \text{left}[p] − |wux|\), then the longest suffix-palindrome is
also preceded by the reversed prefix of \((wux)^\infty\) of length \(d''\) but \(d ≥ d''\) in general. However,
even in this case, we can use \(d''\) in the sequel since none of the suffix-palindromes from
our series survives after n − \text{left}[p] − |wux| predictable extensions; therefore, also, the possible
processing of a suffix-palindrome of length n − \text{left}[p] − d'' mentioned above is not required.
Let us track the set \( S = \{ \ell_1 = n - \text{len}(x_1) + 1, \ldots, \ell_k = n - \text{len}(x_k) + 1 \} \) of the leftmost positions of the suffix-palindromes centered at \( x_1, x_2, \ldots, x_k \) in the \( d' \) predictable extensions: all these positions shift to the left by one after each extension; if a position reaches \( \text{left}[p] \), the corresponding palindrome dies and this position is excluded from \( S \). By Lemma 3, for any \( i \in [1..k] \), if \( \ell_i \) is in the set after \( f \in [0..d'] \) predictable extensions, then the suffixes \( s[\ell_i + jp..n] \) (here \( n \) is increased by \( f \)) are palindromes for all integers \( j \geq 0 \) such that \( \ell_i + jp \leq n \); therefore, along with the assignments \( \text{ans}[n] \leftarrow \text{min} \{1 + \text{ans}[\ell_i - 1] \} \) (here \( n \) is increased by \( f \)) that we are intended to perform, we can occasionally perform \( \text{ans}[n] \leftarrow 1 + \text{ans}[\ell_i + jp - 1] \) for any such \( j \).

Obviously, \( |u_1| + p > n - \text{left}[p] \) since otherwise \( uu u_1 \) would be a longer suffix-palindrome with the minimal period \( p \). Based on the above observation, we perform the assignments \( \text{ans}[n+j] \leftarrow \text{min} \{1 + \text{pre}[r(j)] \} \) for all \( j \in [0..\min\{b, d'\}] \), where \( r(j) = (n - |u_k| - \text{left}[p] - j) \mod p \) (see Fig. 3; \( r(j) \) cyclically runs through the range \([0..p]\) from right to left when \( j \) increases).

Recall that, immediately before the execution of \( \text{predict} \), the function \( \text{precalc} \) recalculates the array \( \text{pre} \). After this recalculation \( \text{pre}[p] \) stores an array \( \text{pre}[p][0..p-1] \) for each \( p \in [1..n] \) such that \( p \) is the minimal period of a suffix-palindrome of \( s[0..n] \). For \( i \in [0..p] \) we have \( \text{pre}[p][i] = \text{min} \{\text{ans}[\text{left}[p] + i + j], j \in [0..\phi_i] \} \), where \( \phi_i \geq 0 \) is the maximal integer such that the string \( s[\text{left}[p] + i + \phi_i, p+1..n] \) has a prefix-palindrome with the minimal period \( p \); if there is no such \( \phi_i \), we put \( \text{pre}[p][i] = +\infty \) and \( \phi_i := -1 \).

We perform \( \text{ans}[n+j] \leftarrow \text{min} \{1 + \text{pre}[r(j)] \} \), for all \( j \in [0..\min\{b, d'\}] \), in \( O(1) \) time using range operations on the arrays \( \text{pre} \) and \( \text{ans} \). (These operations are discussed below.) It follows from Lemma 5 that, after \( f \in [0..d'] \) predictable extensions, the strings \( s[\ell_i..n'] \) (here \( n' \) denotes the value of \( n \) before the extensions), for \( i \in [1..k] \) such that \( \ell_i \) is still in the set \( S \), have prefix-palindromes with the minimal period \( p \). Therefore, the above assignments will really process the palindromes \( u_1, \ldots, u_{k-1} \) for the upcoming \( d' \) predictable extensions (see Fig. 2) but will, probably, perform some additional unnecessary assignments for suffix-palindromes with period \( p \) that will appear only after a number of predictable extensions; but this does not harm since such assignments will be performed anyway in the future. For the baby \( u_k \), we compute explicitly \( \text{ans}[n..n+c] \leftarrow \text{inc}(n - \text{len}(x_k) - c, n - \text{len}(x_k)) \), where \( c = \min\{b, \text{live}(x_k)\} \), in \( O(1) \) time using range operations. It remains to describe the structure of the array \( \text{pre} \) that allows us to perform constant time range operations on subarrays of length \( \leq b \).

**Lemma 6.** For each \( i \in [0..p] \), let \( \phi_i \) be the minimal integer such that the string \( s[\text{left}[p] + i + (\phi_i + 1)p + 1..n] \) has no prefix-palindromes with the minimal period \( p \). Then, the segment \([0..p]\) can be split into subsegments \([k_0..k_1], \ldots, [k_0..k_7] \), for \( 0 = k_0 \leq \cdots \leq k_7 = p \), such that, for \( i \in (0..p) \), we have \( \phi_i = \phi_{i-1} \) whenever \( i \) and \( i - 1 \) belong to the same subsegment (see Fig. 3).
Proof. For $i \in [0..p)$ and $j \geq 0$, denote $i(j) = \text{left}[p]+i+jp$. Let $k$ be an integer such that, for $i = p-1$, we have $i(k) < n$ and $i(k)+p \geq n$. So, for $i \in [0..p)$, we obtain $\phi_i = j'_i - 1$, where $j'_i$ is the minimal integer such that $j'_i \in [0..k]$ and the string $s[i(j'_i)+1..n]$ has no prefix-palindromes with the minimal period $p$. While $i$ descends from $p-1$ to 0 with step one, some of the suffixes $s[i(j)+1..n]$ may acquire prefix-palindromes with the minimal period $p$ and some may lose such prefix-palindromes thus changing the value of $\phi_i$ (see Fig. 3).

Let us choose $i \in [0..p)$ that maximizes the value of $\phi_i$. Denote $j' = \phi_i$ for this $i$. If $j' \geq 0$, then $s[i(j')+1..n]$ has a prefix-palindrome $w$ with the minimal period $p$; by Lemma 3, there are palindromes $u$ and $v$ such that $|uv| = p$ and $w = (uv)^r u$ for $r \geq 1$. Thus, for any $j'' \in [0..j'-2]$, the suffix $s[i(j'')+1..n]$ has prefix-palindromes $(uv)^r u$ and $(uv)^2 u$ both having the minimal period $p$. When $i$ further decreases to 0, the prefix-palindrome $(uv)^2 u$ “grows” together with $s[i(j'')+1..n]$ and, when $i$ increases, $(uv)^3 u$ “shrinks”; in both cases $s[i(j'')+1..n]$ retains a prefix-palindrome with the minimal period $p$ while $i \in [0..p)$. Hence, only suffixes $s[i(j'-1)+1..n]$ and $s[i(j')+1..n]$ may lose or acquire a prefix-palindrome with the minimal period $p$ while $i$ changes from $p-1$ to 0, i.e., $\phi_i$ varies in the range $[j'_{-2..j'}]$.

Let us prove that any suffix $s[i(j)+1..n]$ can lose a prefix-palindrome with the minimal period $p$ at most once during the descending of $i$ from $p-1$ to 0. Then, the existence of the desired numbers $k_0$, $k_1$, ..., $k_T$ follows from a simple analysis of possible cases.

Suppose that $s[i(j)+1..n]$ has a prefix-palindrome centered at $x$ with the minimal period $p$. When $i$ decreases, $s[i(j)+1..n]$ grows and the prefix-palindrome “grows” simultaneously. Then, before $s[i(j)+1..n]$ loses the prefix-palindrome, we have $|s[i(j)+1..n]| = |\text{len}(x)|$ for some $i \in [0..p)$ by Lemma 4, there are palindromes $u'$ and $v'$ such that $|u'v'| = p$ and $s[n-\text{len}(x)+1..n] = (u'v')^r u'$ for $r' \geq 1$. If, for some smaller $i \in [0..p)$, $s[i(j)+1..n]$ again acquires a prefix-palindrome with the minimal period $p$, then, by Lemma 4, the center $x'$ of this prefix-palindrome must coincide with the center of $u'$ or $v'$ from the decomposition. Hence $x' \leq x - p/2$. Then, this prefix-palindrome can be lost only after $p$ decrements of $i$ once we have had $|s[i(j)+1..n]| = |\text{len}(x)|$. This proves the claim.

We partition $\text{pre}[p][0..p-1]$ into subarrays $\text{pre}[p][k_0..k_{-1}-1], \ldots, \text{pre}[p][k_0..k_{-1}-1]$ according to Lemma 6. Consider a segment $[a..b] \subset [0..p)$ such that $\phi_i = \phi_i'$ and $\phi_i' \neq 1$ whenever $i_1, i_2 \in [a..b]$. Since $\text{pre}[p][i] = \min\{|\text{ans}[\text{left}[p]+i+jp]$: $j \in [0..\phi_i']\} \text{ and, by Lemma 2, } |\text{ans}[j]-\text{ans}[j-1]| \leq 1$ for any $j \in [0..n)$, we easily obtain $|\text{pre}[p][i] - \text{pre}[p][i-1]| \leq 1$ for any $i \in (a..b)$. Therefore, by Lemma 6, each of the subarrays of $\text{pre}$ either contains only $\infty$ or has a structure similar to the structure of $\text{ans}$ described in Lemma 2. We do not store the subarrays that contain $\infty$ and encode all other subarrays in a way described for $\text{ans}$ in Sect. 2.4: we split them into blocks of length $b$ and encode each block as its starting element and a $2b$-bit integer encoding the differences between adjacent elements (the last block may contain less than $b$ elements). The linear size of $\text{pre}$ measured in machine words (but not in the number of elements) follows from the overall linear running time of the function $\text{precalc}$ maintaining $\text{pre}$; this analysis is given below.

To perform $\text{ans}[n+j] \leftarrow \min\{\text{pre}[p][r(j)]\}$ for all $j \in [0..\min\{b, d'\}]$, we concatenate $2b$-bit integers from the blocks covering the subarray $\text{ans}[n..n+b]$, $2b$-bit integers from a constant number of blocks covering the subarrays of $\text{pre}[p][0..p-1]$ containing positions $r(j)$ for $j \in [0..\min\{b, d'\}]$, and some other lightweight auxiliary data similar to the data used in the operation $\leftarrow$ considered above; then we compute the resulting array $\text{ans}[n..n+b]$ using the obtained bit string and a precomputed table of size $o(n)$. This might require to duplicate the content of $\text{pre}[p]$ if $p < \min\{b, d'\}$ (see the shaded region in Fig. 2); these duplications must be already precalculated in the tables. Note that thus defined changes of $\text{ans}$ may affect the whole subarray $\text{ans}[n..n+b]$ and not only $\text{ans}[n..n+\min\{b, d'\}]$: e.g., if we
perform $\text{ans}[n] \leftarrow \min x$, then, to maintain the property of $\text{ans}$ described in Lemma 2, we must also perform $\text{ans}[n+j] \leftarrow \min x + j$ for $j \in [1..h]$ (it is guaranteed by the algorithm that the elements of $\text{ans}[0..n-1]$ cannot be affected analogously since always $|\text{ans}[n-1] - \text{ans}[n]| \leq 1$). Similar “normalizations” must be included in the precomputed assignments $\text{ans}[n+j] \leftarrow \min \text{pre}[p][r(j)]$ for all $j \in [0..\min\{b, d\}]$. Thus, the structure of $\text{ans}$ is preserved.

The computations seem to be quite sophisticated but, nevertheless, since all involved structures occupy $\varepsilon \log n$ bits, for $\varepsilon < 1$, all required precalculations can be performed in $O(n^5 \log^{O(1)} n)$ time at the beginning of our algorithm. The tedious details are omitted here and can be retrieved from the implementation [9].

### 3.2 Function precalc

Denote by $n'$ the value of $n$ at the moment of the last call of precalc. (The first call of precalc for $n = 0$ is trivial.) Our goal is to compute the array $\text{pre}[p][0..p-1]$ for each $p$ for which there exists a $p$-series in $s[0..n]$. Note that since, as described above, $\text{pre}[p][0..p-1]$ is stored as a constant number of pointers to subarrays containing non-infinite values, we can fill $\text{pre}[p][0..p-1]$ with $+\infty$ in $O(1)$ time simply removing all these pointers.

The function precalc loops through all series in $s[0..n]$ and processes each $p$-series as follows: precalc computes the new value of $\text{left}[p]$ in $O(1)$ time and, if $\text{left}[p]$ has changed since $s[0..n']$ (this is where we really use the array left), then fills $\text{pre}[p][0..p-1]$ with $+\infty$ in $O(1)$ time; otherwise, precalc uses the array $\text{pre}[p][0..p-1]$ calculated for $s[0..n']$. In either case, for each $i \in [0..p)$, if there is an integer $j \geq 0$ such that $s[\text{left}[p] + i + jp..n']$ does not have a prefix-palindrome with the minimal period $p$ and $s[\text{left}[p] + i + j \cdot p..n']$ has such a prefix-palindrome, then $\text{pre}[p][i]$ is updated by performing $\text{pre}[p][i] \leftarrow \min \text{ans}[\text{left}[p] + i + j \cdot p..n']$. The methods by which we find such $i \in [0..p)$ and really perform the later assignments are described below. It follows from the definition of pre that thus defined precalc computes the arrays $\text{pre}[p][0..p-1]$ for $s[0..n]$.

Let us process all centers $x$ for which there are $i \in [0..p)$ and $j \geq 0$ such that $x$ is the center of a prefix-palindrome of $s[\text{left}[p] + i + j \cdot p..n']$ with the minimal period $p$ but $s[\text{left}[p] + i + j \cdot p..n']$ does not have a prefix-palindrome with the minimal period $p$. We consider two cases.

#### Case 1

Suppose that such $x$ is less than $n'+1$ and the longest subpalindrome $w$ in $s[0..n']$ centered at $x$ has the minimal period $p$. Clearly, the leftmost position of $w$ is greater than $\text{left}[p] + i + jp$ and $w$ must be a suffix-palindrome of $s[0..n']$. Let us describe all positions $h_m = n' - |w| - m$ such that $x$ is the center of a prefix-palindrome of $s[h_m + 1..n]$ and is not the center of a prefix-palindrome of $s[h_m + 1..n']$. Obviously $m > 0$. After $n' - |w| - \text{left}[p] + 1$ extensions of $s[0..n']$, the suffix-palindrome centered at $x$ dies because it reaches $\text{left}[p]$ by its leftmost position (see Fig. 4). So, since $w$ grows at most $n - n'$ times, we obtain $m \in [1..\min\{n-n', n' - |w| - \text{left}[p]\}]$. For each such $m$, the prefix-palindrome of $s[h_m + 1..n]$ centered at $x$ has length $|w| + 2m$ and the minimal period $p$ since the minimal period of $w$, centered at $x$, is $p$ and the palindromic with the length $|w| + 2m$ and the center $x$, for the given $m$, is a substring of the suffix of $s$ with period $p$. Hence, we can perform
with the center

The function

period breaks. Since

extensions, such palindrome dies since it reaches

lists of the centers of all suffix-palindromes

in the list of the centers of all suffix-palindromes. The iterator maintains such list. The

suffix-palindromes with a given period

Lemma 3, is extended by the letter

Growing suffix-palindromes acquire new minimal periods, we need a device tracking changes

of subpalindrome with the minimal period

Case 2. It remains to detect all x such that x is the center of a prefix-palindrome of

s[\left(p+i+j\right)\ldots n] with the minimal period p, for some i \in \{0..p\} and j \geq 0, and either x > n' or the minimal period of any subpalindrome in s[0..n'] centered at x is not p. Hence, a subpalindrome with the minimal period p and the center x appeared after several extensions of s[0..n'] and, thus, was a suffix-palindrome at that moment. To catch the moments when growing suffix-palindromes acquire new minimal periods, we need a device tracking changes of periods in all suffix-palindromes after extensions. The iterator can serve as such a device.

Let w be a suffix-palindrome of s[0..n'] with the minimal period p'. By Lemma 3, we have

p' = |w| - |u|, where u is the longest proper suffix-palindrome of w. Suppose that s[0..n'] is extended by the letter a = s[n'+1] and awa is a suffix-palindrome of the new string. By Lemma 3, awa has period p' iff awa is a suffix-palindrome of s[0..n'+1]. Thus, to detect new suffix-palindromes with a given period p, we can track, during the extensions of s, changes in the list of the centers of all suffix-palindromes. The iterator maintains such list. The following lemma is a straightforward corollary of the proof of [7, Prop. 1].

Lemma 7. The iterator maintains a linked list of the centers of all suffix-palindromes of s[0..n]. The function add(a) removes a number of centers from the list, adds the centers

n + \frac{1}{2} (if a = s[n]) and n+1 to the end of the list, and thus obtains a new list for the string s[0..n][a] all in \Omega(1 + c) time, where c is the number of removed centers.

We maintain an instance of the iterator for the previously processed string s[0..n'] and store the list of the centers of all suffix-palindromes of s[0..n'] since the last call of precalc. The function precalc performs add(s[n'+1]), \ldots, add(s[n]) and thus consecutively obtains the lists of the centers of all suffix-palindromes of s[0..n'+1], \ldots, s[0..n].

Consider, for n'' \in (n',..n], such list x_1, \ldots, x_k for s[0..n''-1] so that

x_1 < \cdots < x_k. By Lemma 7, the call to add(s[n'']) gives us a sublist x_{i_1}, \ldots, x_{i_c} of the centers removed from

x_1, \ldots, x_k. By Lemma 3, for x_i \not\in \{x_1, \ldots, x_{i_c}\} the minimal period of the suffix-palindrome

with the center x_i has changed if x_{i+1} \in \{x_1, \ldots, x_{i_c}\}. We easily find all such x_i parsing the

list x_1, \ldots, x_k from left to right and compute the new period as p = len(x_i) - len(nextPal(x_i)).

Denote by \ell the number that is equal to len(x_i) for s[0..n'']. By the definition of pre, we must perform

\text{pre}[\text{left}[p] + i] \leftarrow \text{ans}[n' - \ell], where r = (n'' - \ell - \text{left}[p]) \mod p, if the string s[0..n'] has a p-series. In this case, we must also perform \text{pre}[\text{left}[p] + (r - m) \mod p] \leftarrow \text{ans}[n'' - \ell - m]

for all m \in \{0..\min(n - n', n'' - \ell - \text{left}[p])\} because the strings s[n'' - \ell - m..n] have suffix-palindromes of length \ell + 2m centered at x_i with the minimal period p; after n'' - \ell - \text{left}[p] + 1 extensions, such palindromes dies since it reaches \text{left}[p] by its leftmost position and thus its period breaks. Since n - n'' \leq b, these assignments, for all such m, can be performed by
range operations on pre and ans in $O(1)$ time using precomputed tables like those described in Sect. 2.4 (subarrays of pre[p] can be also adjusted appropriately).

Thus, precalc works in $O(t + q)$ time as required, where $t$ is the number of series in $s[0..n]$ and $q$ is the time required to perform the sequence of calls $\text{add}(s[p'+1]), \ldots, \text{add}(s[n])$. This finishes the proof of the linear time complexity of main algorithm.

Abstract

A substring $Q$ of a string $S$ is called a shortest unique substring (SUS) for interval $[s, t]$ in $S$, if $Q$ occurs exactly once in $S$, this occurrence of $Q$ contains interval $[s, t]$, and every substring of $S$ which contains interval $[s, t]$ and is shorter than $Q$ occurs at least twice in $S$. The SUS problem is, given a string $S$, to preprocess $S$ so that for any subsequent query interval $[s, t]$ all the SUSs for interval $[s, t]$ can be answered quickly. When $s = t$, we call the SUSs for $[s, t]$ as point SUSs, and when $s \leq t$, we call the SUSs for $[s, t]$ as interval SUSs. There exist optimal $O(n)$-time preprocessing scheme which answers queries in optimal $O(k)$ time for both point and interval SUSs, where $n$ is the length of $S$ and $k$ is the number of outputs for a given query. In this paper, we reveal structural, combinatorial properties underlying the SUS problem: Namely, we show that the number of intervals in $S$ that correspond to point SUSs for all query positions in $S$ is less than $1.5n$, and show that this is a matching upper and lower bound. Also, we consider the maximum number of intervals in $S$ that correspond to interval SUSs for all query intervals in $S$.

1 Introduction

1.1 Shortest unique substring (SUS) problems

A substring $Q$ of a string $S$ is called a shortest unique substring (SUS) for interval $[s, t]$ in $S$, if (1) $Q$ occurs exactly once in $S$, (2) this occurrence of $Q$ contains interval $[s, t]$, and (3) every substring of $S$ which contains interval $[s, t]$ and is shorter than $Q$ occurs at least twice in $S$. The SUS problem is to preprocess a given string $S$ so that for any subsequent query interval $[s, t]$, SUSs for interval $[s, t]$ can be answered quickly. When $s = t$, a query $[s, t]$ refers to a single position in the string $S$, and the problem is specifically called the point SUS problem. For clarity, when $s \leq t$, the problem is called the interval SUS problem.

Pei et al. [5] were the first to consider the point SUS problem, motivated by some applications in bioinformatics. They considered two versions of this problem, depending on whether a single point SUS has to be returned (the single point SUS problem) or all point SUSs have to be returned (the all point SUSs problem) for a query position.

There is a series of research for the single point SUS problem. Pei et al. [5] gave an $O(n^2)$-time preprocessing scheme which returns a single point SUS for a query position in $O(1)$ time, where $n$ is the length of the input string. Tsuruta et al. [6] and Ileri et al. [3] independently showed optimal $O(n)$-time preprocessing schemes which return a single point SUS for a query position in $O(1)$ time. Hon et al. [1] proposed an in-place algorithm for the same version of the problem, achieving the same bounds as the above solutions.

For the all point SUS problem which is more difficult, Tsuruta et al. [6] and Ileri et al. [3] also showed optimal algorithms achieving $O(n)$ preprocessing time and $O(k)$ query time, where $k$ is the number of all point SUSs for a query point.

Hu et al. [2] were the first to consider the interval SUS problem, and they proposed an optimal algorithm for the interval SUS problem, using $O(n)$ time for preprocessing and $O(k')$ time for queries, where $k'$ is the number of interval SUSs for a query interval. Recently, Mieno et al. [4] proposed an algorithm which solves the interval SUS problem on strings represented by run-length encoding (RLE). If $r$ is the size of the RLE of a given string of length $n$, then $r \leq n$ always holds. Mieno et al.'s algorithm uses $O(r)$ space, requires $O(r \log r)$ time to construct, and answers all SUSs for a query interval in $O(k' + \sqrt{\log r / \log \log r})$ time.

A substring $X$ of a string $S$ is said to be a minimal unique substring (MUS) of $S$, if (i) $X$ occurs in $S$ exactly once and (ii) every proper substring of $X$ occurs at least twice in $S$. All the above algorithms for the SUS problems pre-compute all MUSs of the input string $S$ (or some data structure which is essentially equivalent to MUSs), and extensively use MUSs to return the SUSs for a query position or interval.

Tsuruta et al. [6] showed that the maximum number of MUSs contained in a string of length $n$ is at most $n$. This immediately follows from the fact that MUSs do not nest. Mieno et al. [4] proved that the maximum number of MUSs in a string is bounded by $2r - 1$, where $r$ is the size of the RLE of the string. They also showed a series of strings which have $2r - 1$ MUSs, and hence this bound is tight. These properties played significant roles in designing efficient algorithms for the SUS problems.

On the other hand, structural properties of SUSs are not well understood. A trivial upperbound for the maximum number of intervals that correspond to point SUSs is $3n$, since every MUS can be a SUS for some position of the input string $S$, and for each query position $p$ ($1 \leq p \leq n$), there can be at most 2 SUSs that are not MUSs (one that ends at position $p$ and the other that begins at position $p$).

### 1.2 Our contribution

The main contribution of this paper is matching upper and lower bounds for the maximum number of SUSs for the point SUS problem, which translate to “less than $1.5n$ point SUSs”. Namely, we prove that any string of length $n$ contains at most $(3n - 1)/2$ SUSs for the point SUS problem. We give a series of strings which contains $(3n - 1)/2$ SUSs for any odd number $n \geq 5$. Therefore, our bound is tight, and to our knowledge, this is the first non-trivial result for structural properties of SUSs.

We also consider the maximum number of SUSs for the interval SUS problem. In so doing, we exclude a special case where a query interval $[s, t]$ itself is a unique substring that occurs exactly once in $S$. This is because we have $\Theta(n^2)$ bounds for such trivial SUSs. We then prove that any string of length $n$ contains less than $2n$ non-trivial SUSs for the interval
SUS problem. We also prove that there exists a string of length $n$ which contains $(2 - \varepsilon)n$ non-trivial SUSs for any small number $\varepsilon > 0$.

1.3 Related work

Xu [7] introduced the longest repeat (LR) problem. An interval $[i, j]$ of a string $S$ is said to be an LR for an interval $[s, t]$ if (a) the substring $R = S[i..j]$ occurs at least twice in $S$, (b) the occurrence $[i, j]$ of $R$ contains $[s, t]$ and (c) there does not exist an interval $[i', j']$ of $S$ such that $j' - i' > j - i$, the substring $S[i'..j']$ occurs at least twice in $S$, and the interval $[i', j']$ contains interval $[s, t]$. The point and interval LR problems are defined analogously as the point and interval SUS problems, respectively.

Xu [7] presented an optimal algorithm which, after $O(n)$-time preprocessing, returns all LRs for a given interval in $O(k'')$ time, where $k''$ is the number of output LRs. He claimed that although the point/interval SUS problems and the point/interval LR problems look alike, these problems are actually quite different, with a support from an example where an SUS and LR for the same query point seem rather unrelated. Our $(3n - 1)/2$ bound for the maximum number of SUSs for the point SUS problem also supports his claim in the following sense: In the preprocessing, Xu’s algorithm computes the set of maximal repeats (MR). An interval $[i, j]$ of a string $S$ is said to be an MR if (A) the substring $W = S[i..j]$ occurs at least twice in $S$, and (B) for any $1 \leq i' \leq i \leq j \leq j' \leq n$ with $j' - i' > j - i$, the superstring $Y = S[i'..j']$ of $W$ occurs once in $S$. It is easy to see that the maximum number of MRs is bounded by $n$, since for any position in $S$, there can be at most one MR that begins at that position. This bound is also tight: any even palindrome consisting of $n/2$ distinct characters contains $n$ intervals for which the corresponding substrings are MRs (e.g., for even palindrome $\text{abcdeedcba}$ of length 10, any interval $[i, i]$ for $1 \leq i \leq 10$ is an MR). By definition, any LR of string $S$ is also an MR of $S$. Hence, the maximum number of LRs is also bounded by $n$. Since the above lower bound for MRs with palindromes also applies to LRs, this upper bound for LRs is also tight. Thus, there is a gap of $(n - 1)/2$ between the maximum numbers of SUSs and LRs.

2 Preliminaries

2.1 Notations

Let $\Sigma$ be the alphabet. An element of $\Sigma^*$ is called a string. We denote the length of string $S$ by $|S|$. The empty string is the string of length 0. For any string $S$ of length $n$ and integer $1 \leq i \leq n$, let $S[i]$ denote the $i$th character of $S$. For any $1 \leq i \leq j \leq n$, let $S[i..j]$ denote the substring of $S$ that starts at position $i$ and ends at position $j$ in $S$. For convenience, $S[i..j]$ is the empty string if $i > j$. For any strings $S$ and $w$, let $\#occ_{S}(w)$ denote the number of occurrences of $w$ in $S$, namely, $\#occ_{S}(w) = |\{i : S[i..i+|w|-1] = w\}|$.

2.2 MUSs and SUSs

Let $S$ be any string of length $n$, and $w$ be any non-empty substring of $S$. We say that $w$ is a repeating substring of $S$ if $\#occ_{S}(w) \geq 2$, and that $w$ is a unique substring of $S$ if $\#occ_{S}(w) = 1$. Since any unique substring $w$ of $S$ occurs exactly once in $S$, we will sometimes identify $w$ with its corresponding interval $[i, j]$ such that $w = S[i..j]$. We also say that interval $[i, j]$ is unique if the corresponding $S[i..j]$ is a unique substring of $S$.

A unique substring $w = S[i..j]$ of $S$ is said to be a minimal unique substring (MUS) if any proper substring of $w$ is a repeating substring, namely, $\#occ_{S}(S[i'..j']) \geq 2$ for any $i'$
Tight Bounds on the Maximum Number of Shortest Unique Substrings

Figure 1 For string $S = \text{aabbaababa}$, the set $\mathcal{M}_S = \{[3..4], [4..7], [5..8], [7..9], [8..11]\} = \{\text{bb, baab, aaba, bab, abaa}\}$ of all MUSs of $S$ is shown in the upper part of the diagram. The set $\mathcal{P}_S$ of all SUSs for all positions of string $S$ is shown in the lower part of the diagram. For example, the intervals $[3..6] = \text{baaa}$, $[4..7] = \text{baab}$, $[5..8] = \text{aaba}$, and $[6..9] = \text{abab}$ are SUSs for query position 6, where the first SUS $[3..6]$ is obtained by extending the right-end of MUS $[3..4]$ up to position 6, the second SUS $[4..7]$ and the third $[5..8]$ are MUSs of $S$, and the fourth SUS $[6..9]$ is obtained by extending the left-end of MUS $[8..11]$ up to position 6.

and $j'$ with $i' \geq i$, $j' \leq j$, and $j' - i' < j - i$. Let $\mathcal{M}_S$ be the set of all MUSs in $S$, namely, $\mathcal{M}_S = \{[i, j] : S[i..j] \text{ is a MUS of } S\}$. The next lemma follows from the definition of MUSs.

Lemma 1. No element of $\mathcal{M}_S$ is nested in another element of $\mathcal{M}_S$, namely, any two MUSs $[i, j], [k, \ell] \in \mathcal{M}_S$ satisfy $[i, j] \not\subset [k, \ell]$ and $[k, \ell] \not\subset [i, j]$. Therefore, $0 < |\mathcal{M}_S| \leq n$.

For any substring $S[i..j]$ and an interval $[s, t]$ in $S$, $S[i..j]$ is said to be a shortest unique substring (SUS) for interval $[s, t]$ if
1. $S[i..j]$ is a unique substring of $S$,
2. $[s, t] \subset [i, j]$, and
3. $S[i'..j']$ is a repeating substring of $S$ for any $i', j'$ with $[s, t] \subset [i', j']$ and $j' - i' < j - i$.

In particular, a SUS for some interval $[p, p]$ of length 1 is said to be a SUS for position $p$ and is sometimes referred to as a point SUS in $S$. Also, a SUS for some interval (including those of length 1) is sometimes referred to as an interval SUS in $S$.

Since any SUS $S[i..j]$ occurs in $S$ exactly once, we will sometimes identify it with the interval $[i, j]$ which corresponds to its unique occurrence in $S$.

Clearly, if $[i, j]$ is unique, then $[i, j]$ is the only SUS for the interval $[i, j]$. For any interval $[i, j]$ with $i < j$, if $[i, j]$ is unique and there is no other interval $[s, t] \subset [i, j]$ for which $[i, j]$ is a SUS, then we say that $[i, j]$ is a trivial interval SUS. Also, we say that $[i, j]$ is a non-trivial interval SUS if $[i, j]$ is not a trivial SUS.

For any interval $[s, t] \subset [1, |S|]$, let $\text{SUS}_S([s, t])$ denote the set of interval SUSs of $S$ that contain query interval $[s, t]$, and $\mathcal{I}_S$ the set of all non-trivial interval SUSs of $S$. Also, for any position $p \in [1, |S|]$, let $\text{SUS}_S(p)$ denote the set of point SUSs of $S$ that contain query position $p$, and $\mathcal{P}_S$ the set of all point SUSs of $S$, namely, $\mathcal{P}_S = \bigcup_{p=1}^n \text{SUS}_S(p)$. Figure 1 shows examples of MUSs and SUSs.

Hu et al. [2] showed that it is possible to preprocess a given string $S$ of length $n$ in $O(n)$ time so that later, we can return all SUSs that contain a query interval $[s, t]$ in $O(k)$ time, where $k$ is the number of such SUSs.

As is shown in Lemma 1, the number of MUSs in any string $S$ of length $n$ is bounded by $n$. In this paper, we show that the number of point SUSs in $S$ is less than $1.5n$, more precisely, $|\mathcal{P}_S| \leq (3n - 1)/2$. We will do so by first showing two different bounds on $|\mathcal{P}_S|$ in terms of the number $|\mathcal{M}_S|$ of MUSs in the string $S$, and then merging these two results that lead to the claimed bound. Moreover, this bound is indeed tight, namely, we show
a series of strings containing \((3n - 1)/2\) SUSs. In addition, we show that the number of non-trivial SUSs in \(S\) is less than \(2n\), namely, \(|\mathcal{L}_S| < 2n\). We also prove that there exists a string of length \(n\) which contains \((2 - \varepsilon)n\) non-trivial SUSs for any small number \(\varepsilon > 0\).

### 3 Bounds on the number of point SUSs

Here we show a tight bound for the maximum number of point SUSs in a string. In this section, whenever we speak of SUSs, we mean point SUSs (those for the point SUS problem).

#### 3.1 Upperbound A

In this subsection, we show our first upperbound on the number of SUSs in a string \(S\). In so doing, we define the subsets \(\mathcal{L}_S\), \(\mathcal{M}_S\), and \(\mathcal{R}_S\) of the set \(\mathcal{P}_S\) of all SUS of string \(S\) by

\[
\begin{align*}
\mathcal{L}_S &= \mathcal{P}_S \cap \{ [x, y] \notin \mathcal{M}_S : x < \exists i \leq y \ [i, y] \in \mathcal{M}_S \}, \\
\mathcal{M}_S &= \mathcal{P}_S \cap \mathcal{M}_S, \quad \text{and} \quad \mathcal{R}_S &= \mathcal{P}_S \cap \{ [x, y] \notin \mathcal{M}_S : x \leq \exists j < y \ [x, j] \in \mathcal{M}_S \}.
\end{align*}
\]

Intuitively, \(\mathcal{L}_S\) is the set of SUSs of \(S\) which are not MUSs of \(S\) and can be obtained by extending the beginning positions of some MUSs to the left up to query positions, \(\mathcal{M}_S\) is the set of SUSs of \(S\) which are also MUSs of \(S\), and \(\mathcal{R}_S\) is the set of SUSs of \(S\) which are not MUSs of \(S\) and can be obtained by extending the ending positions of some MUSs to the right up to query positions.

It follows from their definitions that \(\mathcal{L}_S \cap \mathcal{M}_S = \emptyset\), \(\mathcal{M}_S \cap \mathcal{R}_S = \emptyset\), \(\mathcal{R}_S \cap \mathcal{L}_S = \emptyset\) and that \(\mathcal{P}_S = \mathcal{L}_S \cup \mathcal{M}_S \cup \mathcal{R}_S\).

Figure 3 in the next subsection shows examples of \(\mathcal{L}_S\), \(\mathcal{M}_S\), and \(\mathcal{R}_S\) for string \(S = \text{aabbababaa}\). Also compare it with Figure 1 which shows \(\mathcal{P}_S\) for the same string \(S\).

In the proof of the following theorem, we will evaluate the sizes of these three sets \(\mathcal{L}_S\), \(\mathcal{M}_S\), and \(\mathcal{R}_S\) separately.

\[\triangleleft \text{Theorem 2. For any string } S, \ |\mathcal{P}_S| \leq 2|S| - |\mathcal{M}_S|.\]

**Proof.** Let \(n = |S|\) and \(m = |\mathcal{M}_S|\). For any \(1 \leq i \leq m\), let \([b_i, e_i]\) denote the MUS of \(S\) that has the \(i\)th smallest beginning position in \(\mathcal{M}_S\).

It is clear that \(|\mathcal{M}_S| \leq m\). Note that the inequality is due to that fact that some MUS may not be a point SUS for any position in \(S\) (such a MUS is called meaningless in the literature [6]).

Next, we consider the size of \(\mathcal{R}_S\). By definition, for any \([x, y] \in \mathcal{R}_S\), \(x\) is equal to the beginning position of a MUS of \(S\). Therefore, we can bound \(|\mathcal{R}_S|\) by summing up the number of SUSs that begin with \(b_i\) for every \([b_i, e_i] \in \mathcal{M}_S\). For any \(1 \leq i \leq m - 1\), consider two adjacent MUSs \([b_i, e_i]\), \([b_{i+1}, e_{i+1}]\) \(\in \mathcal{M}_S\). Recall that \(b_i < b_{i+1}\). Then, for any \(j \geq e_{i+1}\), the interval \([b_i, j]\) contains both MUSs \([b_i, e_i]\) and \([b_{i+1}, e_{i+1}]\). This implies that \([b_i, j] \notin \mathcal{P}_S\) (see Figure 2), since otherwise both \([b_i, j]\) and \([b_{i+1}, j]\) are SUSs for position \(j\), a contradiction. Thus, for any \([b_i, e_i] \in \mathcal{M}_S\) with \(1 \leq i \leq m - 1\), the number of SUSs that begin with \(b_i\) and belong to \(\mathcal{R}_S\) is at most \(e_{i+1} - e_i - 1\). Also, the number of SUSs that begin with \(b_m\) and belong to \(\mathcal{R}_S\) is at most \(n - e_m\). Consequently, we get \(|\mathcal{R}_S| = \sum_{i=1}^{m-1} (e_{i+1} - e_i - 1) + n - e_m = e_m - e_1 - (m - 1) + n - e_m \leq n - m\).

A symmetric argument gives us the same bound for \(|\mathcal{L}_S|\), namely, \(|\mathcal{L}_S| \leq n - m\). Overall, we obtain \(|\mathcal{P}_S| = |\mathcal{L}_S| + |\mathcal{M}_S| + |\mathcal{R}_S| \leq 2(n - m) + m = 2n - m\). □
Tight Bounds on the Maximum Number of Shortest Unique Substrings

### 3.2 Upperbound B

In this subsection, we provide another upperbound on the size of $\mathcal{PS}_S$.

**Theorem 3.** For any string $S$, $|\mathcal{PS}_S| \leq |S| + |\mathcal{M}_S| - 1$.

To prove Theorem 3, we will use a function $f : \mathcal{PS}_S \to \{1, 2, \ldots, n\}$ and its inverse image $f^{-1} : \{1, 2, \ldots, n\} \to 2^{\mathcal{PS}_S}$. The next lemma is useful to define $f$ and $f^{-1}$.

**Lemma 4.** For any string $S$ and interval $[x, y]$ such that $1 \leq x \leq y \leq |S|$, if $[x, y] \in \mathcal{RS}_S$ then $[x, y] \in \text{SUS}_S(y)$, and if $[x, y] \in \mathcal{LS}_S$ then $[x, y] \in \text{SUS}_S(x)$.

**Proof.** We first prove the former case. Assume on the contrary that some $[x, y] \in \mathcal{RS}_S$ satisfies $[x, y] \not\in \text{SUS}_S(y)$. This implies that there exists a position $p$ in $S$ such that $x \leq p < y$ and $[x, y] \in \text{SUS}_S(p)$. In addition, since $[x, y] \in \mathcal{RS}_S$, there exists a position $q$ such that $x \leq q < y$ and $[x, q] \in \mathcal{M}_S$. Let $z = \max\{p, q\}$. Then, $S[x..z]$ is a unique substring of $S$ which is shorter than $S[x..y]$ and contains position $p$. However, this contradicts that $S[x..y]$ is a SUS for position $p$. Thus, if $[x, y] \in \mathcal{RS}_S$ then $[x, y] \in \text{SUS}_S(y)$. The latter case is symmetric and thus can be shown similarly.

We are now ready to define $f$:

$$f([x, y]) = \begin{cases} x & \text{if } [x, y] \in \mathcal{LS}_S \cup \mathcal{MS}_S, \\ y & \text{if } [x, y] \in \mathcal{RS}_S. \end{cases}$$

Intuitively, the function $f$ charges a given interval $[x, y]$ to its beginning position $x$ if $[x, y]$ is an element of $\mathcal{M}_S \cap \mathcal{PS}_S$ or if $[x, y]$ is an element of $\text{SUS}_S(p)$ for some query position $p$ which is obtained by extending the left-end of a MUS to the left up to $p$. On the other hand, it charges $[x, y]$ to its ending position $y$ if the interval is an element of $\text{SUS}_S(p)$ for some query position $p$ which is obtained by extending the right-end of a MUS to the right up to $p$.

Figure 3 shows examples for how the function $f$ charges given interval $[x, y] \in \mathcal{PS}_S$.

We also define the inverse image $f^{-1}$ of $f$ as follows:

$$f^{-1}(u) = \{[x, y] \in \mathcal{PS}_S : f([x, y]) = u\}.$$

For positions $u$ for which there is no element $[x, y]$ in $\mathcal{PS}_S$ satisfying $f([x, y]) = u$, let $f^{-1}(u) = \emptyset$. See also Figure 3 for examples of $f^{-1}$.
Case where

we analyze Lemma 5.

Hence, neither of the sub-cases is possible.

Proof. Assume w.l.o.g. that $y_1 < y_2$. Then, $[x_2, y_2] = [u, y_2]$ is a SUS for position $u$ but it is longer than another SUS $[x_1, y_1] = [u, y_1]$ for position $u$, a contradiction.

2. Case where $[x_1, y_1], [x_2, y_2] \in \mathcal{MS}_S$: It follows from the definition of $f$ that $f([x_1, y_1]) = f([x_2, y_2]) = u$, and it follows from the definition of $f$ that $x_1 = x_2 = u$. Since $[x_1, y_1]$ and $[x_2, y_2]$ are distinct, $y_1 \neq y_2$. Assume w.l.o.g. that $y_1 < y_2$. Then, $[x_2, y_2] = [u, y_2]$ is a SUS for position $u$, and it follows from the definition of $f$ that $x_1 = x_2 = u$. Since $[x_1, y_1]$ and $[x_2, y_2]$ are distinct, $y_1 \neq y_2$. Assume w.l.o.g. that $y_1 < y_2$. Then, $[x_2, y_2] = [u, y_2]$ is a SUS for position $u$, and it follows from the definition of $f$ that $x_1 = x_2 = u$. Since $[x_1, y_1]$ and $[x_2, y_2]$ are distinct, $y_1 \neq y_2$. There are two sub-cases.

(i) If $y_1 < y_2$, then a MUS $[x_2, y_2] = [u, y_2]$ contains a shorter SUS $[x_1, y_1] = [u, y_1]$ for position $u$, a contradiction.

(ii) If $y_1 > y_2$, then a SUS $[x_1, y_1] = [u, y_1]$ for position $u$ contains a shorter MUS $[x_2, y_2] = [u, y_2]$, a contradiction.

By the definition of $f^{-1}$, it is clear that $|\mathcal{PS}_S| = \sum_{u=1}^{\lvert S \rvert} |f^{-1}(u)|$. Hence, in what follows we analyze $|f^{-1}(u)|$ for all positions $u$ in string $S$.

Lemma 5. For any string and position $1 \leq u \leq \lvert S \rvert$, $|f^{-1}(u)| \leq 2$.

Proof. Assume on the contrary that $|f^{-1}(u)| \geq 3$ for some position $u$ in $S$. Let $[x_1, y_1], [x_2, y_2]$ be any distinct elements of $f^{-1}(u)$. We firstly consider the following cases.

1. Case where $[x_1, y_1], [x_2, y_2] \in \mathcal{LS}_S$: It follows from the definition of $f^{-1}$ that $f([x_1, y_1]) = f([x_2, y_2]) = u$, and it follows from the definition of $f$ that $x_1 = x_2 = u$. Since $[x_1, y_1]$ and $[x_2, y_2]$ are distinct, $y_1 \neq y_2$. Assume w.l.o.g. that $y_1 < y_2$. Then, $[x_2, y_2] = [u, y_2]$ is a SUS for position $u$ but it is longer than another SUS $[x_1, y_1] = [u, y_1]$ for position $u$, a contradiction.

2. Case where $[x_1, y_1], [x_2, y_2] \in \mathcal{MS}_S$: It follows from the definition of $f^{-1}$ that $f([x_1, y_1]) = f([x_2, y_2]) = u$, and it follows from the definition of $f$ that $x_1 = x_2 = u$. Since $[x_1, y_1]$ and $[x_2, y_2]$ are distinct, $y_1 \neq y_2$. Assume w.l.o.g. that $y_1 < y_2$. Then, $[x_2, y_2] = [u, y_2]$ is a SUS for position $u$, and it follows from the definition of $f$ that $x_1 = x_2 = u$. Since $[x_1, y_1]$ and $[x_2, y_2]$ are distinct, $y_1 \neq y_2$. There are two sub-cases.

(i) If $y_1 < y_2$, then a MUS $[x_2, y_2] = [u, y_2]$ contains a shorter SUS $[x_1, y_1] = [u, y_1]$ for position $u$, a contradiction.

(ii) If $y_1 > y_2$, then a SUS $[x_1, y_1] = [u, y_1]$ for position $u$ contains a shorter MUS $[x_2, y_2] = [u, y_2]$, a contradiction.

Hence, neither of the sub-cases is possible.

Overall, we conclude that $|f^{-1}(u)| \leq 2$.  

**Figure 3** Illustration for functions $f$ and $f^{-1}$ of string $S = \text{aabbaababa}$. The upper part of this diagram shows all MUSs in $S$, and the lower part shows all SUSs for all positions in $S$. Each star shows the position to which the function $f$ maps the corresponding interval. Here, $\mathcal{RS}_S = \{[3, 5], [3, 6], [7, 10]\}$, $\mathcal{MS}_S = \{[3, 4], [4, 7], [5, 8], [7, 9], [8, 11]\}$, and $\mathcal{LS}_S = \{[1, 4], [2, 4], [6, 10]\}$.

Hence, we have $f([3, 5]) = 5, f([3, 6]) = 6, f([7, 10]) = 10, f([3, 4]) = 3, f([4, 7]) = 4, f([5, 8]) = 5, f([7, 9]) = 7, f([8, 11]) = 8, f([1, 4]) = 1, f([2, 4]) = 2$, and $f([6, 10]) = 6$. For the inverse image, $f^{-1}$, we have $f^{-1}(1) = \{[1, 4]\}, f^{-1}(2) = \{[2, 4]\}, f^{-1}(3) = \{[3, 4]\}, f^{-1}(4) = \{[4, 7]\}, f^{-1}(5) = \{[3, 5], [5, 8]\}, f^{-1}(6) = \{[3, 6], [6, 10]\}, f^{-1}(7) = \{[7, 9]\}, f^{-1}(8) = \{[8, 11]\}, f^{-1}(9) = f^{-1}(11) = \emptyset$, and $f^{-1}(10) = \{[7, 10]\}$.
By Lemma 5, for any position \( u \) in string \( S \) we have \( |f^{-1}(u)| \leq 2 \). Now let us consider any position \( u \) for which \( |f^{-1}(u)| = 2 \). We have the next lemma.

**Lemma 6.** For any position \( u \) in string \( S \) for which \( |f^{-1}(u)| = 2 \), let \( f^{-1}(u) = \{[x_1,y_1],[x_2,y_2]\} \) and assume w.l.o.g. that \( x_1 \leq x_2 \). Then, \( x_1 \neq x_2 \), \( [x_1,y_1] \in \mathcal{RS}_S \) and \( [x_2,y_2] \in \mathcal{LS}_S \cup \mathcal{MS}_S \).

**Proof.** Suppose \( x_1 = x_2 \) and assume w.l.o.g. that \( y_1 < y_2 \). Then, from the definition of \( f \), we have that \( (x_1 = u \text{ or } y_1 = u) \) and \( (x_2 = u \text{ or } y_2 = u) \) and thus \( x_1 = x_2 = u \). Since \( [x_2,y_2] \in f^{-1}(u) \) is not a MUS since it includes \( [x_1,y_1] \), it must be that \( [x_2,y_2] \in \mathcal{SUS}(u) \). This is a contradiction, because there exists a shorter unique substring \([x_1,y_1]\) that contains \( u \). Thus we have \( x_1 \neq x_2 \). Assume on the contrary that \( [x_1,y_1] \notin \mathcal{LS}_S \cup \mathcal{MS}_S \). Then, it follows from the definition of \( f \) that \( f([x_1,y_1]) = x_1 \). In addition, since \( [x_1,y_1] \in f^{-1}(u) \), we have \( u = x_1 \). This implies that \( u = x_1 < x_2 \), but it contradicts that \([x_2,y_2] \in f^{-1}(u) \). Thus, \([x_1,y_1] \notin \mathcal{LS}_S \cup \mathcal{MS}_S \), namely, \([x_1,y_1] \notin \mathcal{RS}_S \). Now, it follows from the arguments in the proof of Lemma 5 that \([x_2,y_2] \notin \mathcal{RS}_S \), and hence \([x_2,y_2] \in \mathcal{MS}_S \cup \mathcal{LS}_S \). \(\blacksquare\)

Let \( m = |\mathcal{MS}_S| \), and \( \mathcal{MS} = \{[b_1,e_1],\ldots,[b_m,e_m]\} \). The next corollary immediately follows from Lemmas 4 and 6.

**Corollary 7.** For any position \( u \) in string \( S \) with \( |f^{-1}(u)| = 2 \), there exist two integers \( 1 \leq i < j \leq m \) such that \( \mathcal{SUS}(u) = \{[b_i,u],[u,e_j]\} \).

For any position \( u \) in string \( S \) before \( b_1 \) or after \( b_m \), we have the next lemma.

**Lemma 8.** For any position \( u \) in string \( S \) s.t. \( 1 \leq u \leq b_1 \) or \( b_m < u \leq n \), \( |f^{-1}(u)| \leq 1 \).

**Proof.** Assume on the contrary that \( |f^{-1}(u)| \geq 2 \) for some \( 1 \leq u \leq b_1 \). By Lemma 6, there exists \([x,y] \in f^{-1}(u)\) such that \([x,y] \in \mathcal{RS}_S \). By the definition of \( f \) and \( f^{-1} \), we have \( y = u \). Also, by the definition of \( \mathcal{RS}_S \), there exists a position \( e < y \in S \) such that \([x,e] \in \mathcal{MS} \). Now we have \( x \leq e < y = u \leq b_1 \), however, this contradicts that \( b_1 \) is the beginning position of the first (leftmost) MUS in \( \mathcal{MS} \). Thus \( |f^{-1}(u)| \leq 1 \) for any \( 1 \leq u \leq b_1 \).

Assume on the contrary that \( |f^{-1}(u)| \geq 2 \) for some \( b_m < u \leq n \). By Lemma 6, there exists \([x',y'] \in f^{-1}(u)\) such that \([x',y'] \in \mathcal{MS} \cup \mathcal{LS}_S \). By the definition of \( f \) and \( f^{-1} \), we have \( x' = u \). There are two cases to consider:

- If \([x',y'] \in \mathcal{MS} \), then \([x',y'] \in \mathcal{MS} \). Thus \( x' = u > b_m \) is the beginning position of a MUS in \( \mathcal{MS} \), however, this contradicts that \( b_m \) is the beginning position of the last (rightmost) MUS in \( \mathcal{MS} \).
- If \([x',y'] \in \mathcal{LS}_S \), then by the definition of \( \mathcal{LS}_S \) there exists a position \( b > x' \) such that \([b,y'] \in \mathcal{MS} \). Now we have \( b > x' = u > b_m \), however, this contradicts that \( b_m \) is the beginning position of the last (rightmost) MUS in \( \mathcal{MS} \).

Consequently, \( |f^{-1}(u)| \leq 1 \) for any \( b_m < u \leq n \). \(\blacksquare\)

**Lemma 9.** For any non-empty string \( S \), let \( U = \{u : |f^{-1}(u)| = 2\} \). Then, \( |U| \leq |\mathcal{MS}| - 1 \).

**Proof.** Let \( n = |S| \) and \( m = |\mathcal{MS}| \). Recall that for any \( 1 \leq i \leq m \), \([b_i,e_i]\) denotes the \( i \)th element of \( \mathcal{MS} \).

Let \( B = \{b_i : 1 \leq i \leq m - 1\} \). We define function \( g : U \rightarrow B \) as \( g(u) = \max\{b < u : b \in B\} \). By the definition of \( U \) and Lemma 8, any position \( u \in U \) satisfies \( b_1 < u \leq b_m \). Therefore, \( g(u) \) is well-defined for any position \( u \in U \), and \( g(u) \) returns the predecessor of \( u \) in the set \( B \). It is clear that \( |B| = m - 1 \). Thus, if \( g \) is an injection, then we immediately obtain the claimed bound \( |U| \leq |B| = m - 1 \).
by Theorem 2, we have

\[ |M| \leq |S| + 1 \leq |M_S| \]

We are ready to prove the main result of this subsection, Theorem 3.

**Proof.** Let \( n = |S|, m = |M_S|, U = \{ u : |f^{-1}(u)| = 2 \}, V = \{ 1, \ldots, n \} \setminus U. \) It is clear that \( |U| + |V| = n. \) By Lemma 5, \( V = \{ u : |f^{-1}(u)| \leq 1 \}. \) Also, by Lemma 9, \( |U| \leq m - 1. \) Recall that \( |PS_S| = \sum_{u=1}^{n} |f^{-1}(u)|. \) Putting all together, we obtain \( |PS_S| = \sum_{u=1}^{n} |f^{-1}(u)| \leq |V| + 2|U| = n + |U| \leq n + m - 1. \)

### 3.3 Matching upper and lower bounds

We are ready to show the main result of this paper.

**Theorem 10.** For any non-empty string \( S, \) \( |PS_S| \leq (3|S| - 1)/2. \) This bound is tight, namely, for any odd \( n \geq 5 \) there exists a string \( T \) of length \( n \) s.t. \( |PS_T| = (3n - 1)/2. \)

**Proof.** By Theorem 2, we have \( |M_S| \leq 2|S| - |PS_S|. \) Also, by Theorem 3, we have \( |PS_S| - |S| + 1 \leq |M_S|. \) Thus \( |PS_S| - |S| + 1 \leq 2|S| - |PS_S|, \) which immediately leads to the claimed bound \( |PS_S| \leq (3|S| - 1)/2. \)

We show that the above upperbound is indeed tight. For any odd number \( n = 2k - 1 \geq 5, \) consider string \( T = a_1x a_2 x \cdots a_{k-1} x a_k, \) where \( a_1, \ldots, a_k, x \in \Sigma, a_i \neq a_j \) for all \( 1 \leq i \neq j \leq k, \) and \( x \neq a_i \) for all \( 1 \leq i \leq k. \) For any \( 1 \leq i \leq k, T[2i - 1] = a_i \) is a unique substring of \( T, \) and thus \( T[2i - 1, 2i - 1] \in SUS_T(2i - 1). \) Also, for any \( 1 \leq i \leq k - 1, T[2i+1] = x \) is a repeating substring of \( T \) while \( T[2i+1 - 1, 2i + 1] = a_ix \) and \( T[2i+1, 2i + 1] = a_ixa_i+1 \) are unique substrings of \( T. \) This implies that \( |PS_T| = k + 2(k - 1) = 3k - 2 = 3(n+1)/2 - 2 = (3n - 1)/2. \)
3.4 Lower bound for fixed-size alphabet

The lower bound of Theorem 10 is due to a series of strings over an alphabet of unbounded size. In this subsection, we fix the alphabet size $\sigma$ and present a series of strings that contain many point SUSs.

**Theorem 11.** Let $n \geq 2$ and $2 \leq \sigma \leq (n+3)/2$. There exists a string $T$ of length $n$ over an alphabet of size $\sigma$ such that $|\mathcal{PS}_T| = n + \sigma - 2$.

**Proof.** Let $\Sigma = \{a_1, \ldots, a_{\sigma-1}, x\}$ and $T = a_1xa_2x \cdots a_{\sigma-1}x^2\sigma+3$. For any $1 \leq i \leq \sigma - 1$, $T[2i-1] = a_i$ is a unique substring of $T$, and thus $[2i-1, 2i-1] \in \text{SUS}_T(2i-1)$. For any $1 \leq j \leq \sigma - 2$, $T[2j] = x$ is a repeating substring of $T$ while $T[2j-1..2j] = a_jx$ and $T[2j..2j+1] = xa_{j+1}$ are unique substrings of $T$. This implies that $[2j-1, 2j], [2j, 2j+1] \in \text{SUS}_T(2j)$. For any $2\sigma - 2 \leq k \leq n - 1$, $T[2\sigma - 2..k] = x^{k-2\sigma+3}$ is a repeating substring of $T$ while $T[2\sigma-1..k] = a_{\sigma-1}x^{k-2\sigma+3}$ is a unique substring of $T$. This implies that $[2\sigma - 1, k] \in \text{SUS}_T(k)$. Also, $T[2\sigma - 1..n] = x^{n-2\sigma+2}$ is a repeating substring of $T$ and $T[2\sigma - 2..n] = x^{n-2\sigma+3}$ is a unique substring of $T$, and thus $[2\sigma - 2..n] \in \text{SUS}_T(n)$. Summing up all the point SUSs above, we obtain $|\mathcal{PS}_T| = \sigma - 1 + 2(\sigma - 2) + n - 2\sigma + 2 + 1 = n + \sigma - 2$. ▶

4 Bounds on the number of interval SUSs

In this section, we show almost tight bounds for the maximum number of non-trivial interval SUSs $\mathcal{IS}_S$ of a string $S$. The following upper bound for $|\mathcal{IS}_S|$ can be obtained in an analogous way to Theorem 2.

**Lemma 12.** For any non-empty string $S$, $|\mathcal{IS}_S| \leq 2|S| - |\mathcal{M}_S|$.

We also have the following lower bound for $|\mathcal{IS}_S|$.

**Lemma 13.** For any $\epsilon > 0$, there exists a string $T$ of length $n$ such that $|\mathcal{IS}_T| > (2 - \epsilon)n$.

**Proof.** Let $x = \lfloor 3/(2\epsilon) \rfloor, T = c_1x^2c_2x^2c_3$ and $n = |T| = 2x + 3$. Clearly, $c_1, c_2$ and $c_3$ are MUSs of $T$ and are in $\mathcal{IS}_T$. For all $2 \leq i \leq x + 1$, $T[1..i]$ and $T[i..x+2]$ are unique substrings of $T$, and $T[2..i]$ and $T[i..x+1]$ are repeating substrings of $T$. This implies $T[1..i] \in \text{SUS}_S([2, i])$ and $T[i..x+2] \in \text{SUS}_S([i, x + 1])$. Similarly, for all $x + 3 \leq j \leq 2x + 2$, $T[x+2..j] \in \text{SUS}_S([x+3, j])$ and $T[j..x+2] \in \text{SUS}_S([j, x+2])$. Then, we have $|\mathcal{IS}_T| = 4x + 3$. Hence, $|\mathcal{IS}_T| - (2 - \epsilon)n = 4x + 3 - (2 - \epsilon)(2x + 3) = 2\epsilon x + 3\epsilon - 3 = 2\epsilon \left(\frac{3}{2\epsilon}\right) + 3\epsilon - 3 \geq 3\epsilon > 0$. ▶

As is shown in the following theorem, the number of non-trivial interval SUSs contained in the string $T$ of Lemma 13 “almost coincides” with the upper bound of Lemma. Namely:

**Theorem 14.** For any $\epsilon > 0$, there is a string $T$ such that $(2|T| - |\mathcal{M}_T|) - (2 - \epsilon)|T| \leq 5\epsilon$.

**Proof.** For any $\epsilon > 0$, consider the string $T$ of Lemma 13. We remark that $T$ contains 3 MUSs, namely, $|\mathcal{M}_T| = 3$. Hence, we obtain $(2|T| - |\mathcal{M}_T|) - (2 - \epsilon)|T| = \epsilon|T| - |\mathcal{M}_T| = \epsilon|T| - 3 = \epsilon(2\left(\frac{3}{2}\right) + 3) - 3 = 2\epsilon \left(\frac{3}{2}\right) + 3\epsilon - 3 = 2\epsilon \left(\frac{3}{2}\right) + 3\epsilon - 3 = 5\epsilon - 0 (\epsilon \rightarrow 0)$. ▶

5 Conclusions and open questions

In this paper, we presented matching upper and lower bounds for the maximum number of SUSs for the point SUS problem. Namely, we proved that any string of length $n$ can contain at most $(3n - 1)/2$ SUSs for the point SUS problem, and showed that this bound is tight by giving a string of length $n$ containing $(3n - 1)/2$ SUSs. For a fixed alphabet size $\sigma$, we
also presented a string of length $n$ containing $n + \sigma - 2$ SUSs. Moreover, we showed that any string of length $n$ which contains $m$ MUSs can have at most $2n - m$ non-trivial interval SUSs, and that for any $\varepsilon > 0$ there is a string of length $n$ which contains $(2 - \varepsilon)n$ non-trivial interval SUSs.

An interesting future work is to show a non-trivial upper bound of the maximum number of point SUSs for a fixed alphabet size $\sigma$. We conjecture that the tight upper bound matches our lower bound $n + \sigma - 2$. Another future work is to close the small gap between the upper and lower bounds on the maximum number of non-trivial interval SUSs shown in Theorem 14.

Abstract
Data analysis typically involves error recovery and detection of regularities as two different key tasks. In this paper we show that there are data types for which these two tasks can be powerfully combined. A common notion of regularity in strings is that of a cover. Data describing measures of a natural coverable phenomenon may be corrupted by errors caused by the measurement process, or by the inexact features of the phenomenon itself. Due to this reason, different variants of approximate covers have been introduced, some of which are \( \text{NP} \)-hard to compute. In this paper we assume that the Hamming distance metric measures the amount of corruption experienced, and study the problem of recovering the correct cover from data corrupted by mismatch errors, formally defined as the cover recovery problem (CRP). We show that for the Hamming distance metric, coverability is a powerful property allowing detecting the original cover and correcting the data, under suitable conditions.

We also study a relaxation of another problem, which is called the approximate cover problem (ACP). Since the ACP is proved to be \( \text{NP} \)-hard [5], we study a relaxation, which we call the candidate-relaxation of the ACP, and show it has a polynomial time complexity. As a result, we get that the ACP also has a polynomial time complexity in many practical situations. An important application of our ACP relaxation study is also a polynomial time algorithm for the cover recovery problem (CRP).

1 Introduction
Data analysis typically involves error recovery and detection of regularities as two different key tasks. In this paper we show that there are data types for which these two tasks can be powerfully combined. A classical tool for handling data recovery is through the use of error correcting codes. Error correcting codes are an invaluable method of adding redundancy to data so that the initial data can be recovered even after the introduction of a bounded number of errors. Errors in raw natural data with no prior knowledge of its structure are
Can We Recover the Cover?

usually considered beyond the feasible scope of recovery. Nonetheless, it was recently [4] shown, that data regularity, even if its structure is unknown a-priori, can serve as an aid to error recovery.

Regularities in strings arise in various areas of science, including coding and automata theory, formal language theory, combinatorics, molecular biology and many others. A typical form of regularity is periodicity, meaning that a “long” string \( T \) can be represented as a concatenation of copies of a “short” string \( P \), possibly ending in a prefix of \( P \). Periodicity has been extensively studied in Computer Science over the years (see [28]).

1.1 Regularities and Data Recovery

Recently, it was shown [4] that periodicity can serve as an aid to error recovery. It was proven that if no more than \( n \left( 1 + \epsilon \right) \) mismatch errors are introduced to a periodic string of length \( n \) having period of length \( p \) then, even if \( p \) is not known a-priori, it is possible to recover \( O(\log n) \) possible candidates, one of which is guaranteed to be the original period. This surprising result was further reinforced by discovering that a similar result holds not just for mismatch error corruptions bounded by the Hamming distance, but for any errors bounded by a pseudo local metric (e.g. the swap or interchange metrics). An interesting additional result was that even under some non-pseudo local metrics, such as the edit distance, periodicity can still allow recovery of \( O(\log n) \) candidate periods [4, 2]. However, these candidate periods are distinguished in that none are cyclic rotations of each other. In other words, if we take one representative of all candidates that are cyclic rotations of each other, we end up with the small number of candidates. It was unknown whether there are other regularities in natural phenomena that allow recovery of the original string. Identifying such a type of regularity is the first topic of this paper.

In particular, for many phenomena, it is desirable to broaden the definition of periodicity and study wider classes of repetitive patterns in strings. One common such notion is that of a cover, defined as follows.

Definition 1 (Cover). A length \( m \) substring \( C \) of a string \( T \) of length \( n \), is said to be a cover of \( T \), if \( n > m \) and every letter of \( T \) lies within some occurrence of \( C \).

Note that the string \( C \) is both a prefix and a suffix of the string \( T \). For example, consider the string \( T = abababababa \). Clearly, \( T \) is “almost” periodic with period \( aba \), however, as it is not completely periodic, the algorithms that exploit repetitions cannot be applied to it. On the other hand, the string \( C = aba \) is a cover of \( T \), which allows applying to \( T \) cover-based algorithms. We study error correction feasibility for coverable phenomena.

1.2 Related Work

We review related regularity types and other approaches to handle errors in regularities. Quasi-periodicity was introduced by Ehrenfeucht in 1990 (according to [7]). The earliest paper in which it was studied is by Apostolico, Farach and Lliopoulos [9], which defined the quasi-period of a string to be the length of its shortest cover and presented an algorithm for computing the quasi-period of a given string in \( O(n) \) time and space. The new notion attracted immediately several groups of researchers (e.g. [10], [29, 30], [27], [11]). An overview on the first decade of the research on covers can be found in the surveys [7, 20, 32].

While covers are a significant generalization of the notion of periods as formalizing regularities in strings, they are still restrictive, in the sense that it remains unlikely that an arbitrary string has a cover shorter than the word itself. Due to this reason, different variants
of quasi-periodicity have been introduced. These include seeds [19], maximal quasi-periodic substring [8], the notion of k-covers [21], λ-cover [33], enhanced covers [16], partial cover [23]. Since the notion of a seed is necessary to our study and presentation of results, we give its formal definition here.

**Definition 2 (Seed).** A length \( m \) substring \( C \) of a string \( T \) of length \( n \), is said to be a seed of \( T \), if \( n > m \) and there exists a superstring \( T' \) of \( T \) such that \( C \) is a cover of \( T' \).

Note that the first and last occurrence of the seed \( C \) in \( T \) may be incomplete. Other recently explored directions include the inverse problem for cover arrays [14], extensions to strings in which not all letters are uniquely defined, such as indeterminate strings [6] or weighted sequences [34]. Some of the related problems are \( \mathcal{NP} \)-hard (see e.g., [6, 12, 23]).

In applications such as molecular biology and computer-assisted music analysis, finding exact repetitions and covers is not always sufficient. A more appropriate notion is that of approximate repetitions, where errors are allowed (see, e.g., [13, 15]). This notion was first studied in 1993 by Landau and Schmidt [25, 26] who concentrated on approximate tandem repeats. Note that, the natural definition of an approximate repetition is not clear. One possible definition is that the distance between any two adjacent repeats is small. Another possibility is that all repeats lie at a small distance from a single “original”. Such a definition of approximate seeds is studied in [12, 18, 17]. Indeed, all these definitions along with other ones were proposed and studied (see [3, 24, 31]). Yet another possibility is that all repeats must be equal, but we allow a fixed total number of mismatches. The possibility presented in [3] is a global one, assuming that an original unknown string is a sequence of repeats without errors, but the process of sequence creation or transmission incurs errors to the sequence of repeats, and, thus, the examined input string is not a sequence of repeats. Therefore, a (smallest) repeat generating a string with the minimum total number of mismatches with the input string is sought. Extension of this definition approach to approximate covers is another topic of this paper.

### 1.3 Our Results

In this paper we show that coverability is also a tool that allows error correction. We formally define the Cover Recovery Problem (CRP) and characterize the feasibility of its solution. In particular, we show:

**Theorem 3.** Let \( S \) be a string coverable by a cover \( C \) of length \( c \), and let \( \varepsilon > 0 \). Assume that at most \( \frac{n}{(2+\varepsilon)c} \) mismatch errors were introduced to \( S \) resulting in a string \( S' \). Then there exist \( O(\log n) \) possible primitive substrings of \( S' \), one of which is guaranteed to be \( C \) or a seed of \( C \).

In addition, extending the approach of [3] to the notion of covers, [5] define the approximate cover problem (ACP), in which we are given a text that is a sequence of some cover repetitions with possible mismatch errors. Since the ACP is proved to be \( \mathcal{NP} \)-hard [5], we study a relaxation of this problem. In our relaxation, which we call the candidate relaxation of the ACP, a candidate cover is also given, and we seek to align it with the given text (this alignment is called a tiling) such that the number of mismatches is minimized. This scenario is quite realistic in the case where a cover is sought for a string where the errors are distributed in a manner that at least one occurrence of the cover appears in the string without errors. We examine this relaxation and show it has polynomial time complexity. As a result, we get that the ACP also has polynomial time complexity in many practical situations. This ACP relaxation study enables also an efficient algorithm for recovering the candidate covers in CRP.
Can We Recover the Cover?

Paper Contributions. The main contributions of this paper are:

- Proving that recovery of raw data from errors is possible not only for periodic phenomena but also for the less rigid coverable phenomena.
- Demonstrating that efficient recovery is feasible even when the underlying problem of computing an approximate cover is \( \mathcal{NP} \)-hard. This is in line with the previous result of [4] that show efficient recovery for the interchange metric, which is \( \mathcal{NP} \)-hard to compute.
- Formalizing the candidate relaxation of the ACP and showing it is polynomial time computable. This study served both to give a solution to the CRP and to suggest an efficient solution for the ACP in many practical situations.

The paper is organized as follows. In Section 2, we give formal definitions and basic lemmas. In Section 3, we study the cover recovery problem (CRP) and characterize the extent to which the cover of the unknown uncorrupted original string can be recovered given the possibly corrupted by mismatch errors input string. In Section 4, we study the candidate relaxation of the ACP with its application to the ACP itself and, more importantly, to the CRP. We conclude with some open problems in Section 5.

2 Preliminaries

In this section we give the needed formal definitions and basic lemmas.

Definition 4 (Tiling). Let \( T \) be a string over alphabet \( \Sigma \) such that the string \( C \) over alphabet \( \Sigma \) is a cover of \( T \). Then, the sorted list of indices representing the start positions of occurrences of the cover \( C \) in the text \( T \) is called the tiling of \( C \) in \( T \).

In this paper we have a text \( T \) which may have been introduced to errors and, therefore, is not coverable. However, we would like to refer to a retained tiling of an unknown string \( C \) in \( T \) although \( C \) does not cover \( T \) because of mismatch positions. The following definition makes a distinction between a list of indices that may be assumed to be a tiling of the text before mismatch errors occurred and a list of indices that cannot be such a tiling.

Definition 5 (A Valid Tiling). Let \( T \) be an \( n \)-length string over alphabet \( \Sigma \) and let \( L \) be a sorted list of indices \( L \subset \{1, \ldots, n\} \). Let \( m = n + 1 - L_{\text{last}} \), where \( L_{\text{last}} \) is the last index in \( L \). Then, \( L \) is called a valid tiling of \( T \), if \( i_1 = 1 \) and for every \( i_k, i_{k+1} \in L \), it holds that \( i_{k+1} - i_k \leq m \).

Notation 1. Let \( C \) be an \( m \)-length string over alphabet \( \Sigma \). Denote by \( S(C) \) a string of length \( n > m \), such that \( C \) is a cover of \( S(C) \).

Note that \( S(C) \) is not uniquely defined even for a fixed \( n > m \), since every different valid tiling of the \( m \)-length string \( C \) generates a different \( n \)-length string \( S(C) \). A unique version can be obtained if a valid tiling \( L \) is also given.

Notation 2. Let \( T \) be an \( n \)-length string over alphabet \( \Sigma \) and let \( L \) be a valid tiling of \( T \). Let \( m = n + 1 - L_{\text{last}} \), where \( L_{\text{last}} \) is the last index in the tiling \( L \). For any \( m \)-length string \( C' \), let \( S_L(C') \) be the \( n \)-length string obtained using \( C' \) as a cover and \( L \) as the tiling as follows: \( S_L(C') \) begins with a copy of \( C' \) and for each index \( i \) in \( L \) a new copy of \( C' \) is concatenated starting from index \( i \) of \( S_L(C') \) (running over a suffix of the last copy of \( C' \) if the difference between \( i \) and the previous index in \( L \) is less than \( m \)).
**Definition 6.** Let $T$ be a string of length $n$ over alphabet $\Sigma$. Let $H$ be the Hamming distance. The distance of $T$ from being covered is:

$$\text{dist} = \min_{C \in \Sigma^*, |C| < n} H(S(C), T).$$

We will also refer to $\text{dist}$ as the number of errors in $T$.

**Definition 7.** Let $T$ be an $n$-long string over alphabet $\Sigma$. An $m$-long string $C$ over $\Sigma$, $m \in \mathbb{N}$, $m < n$, is called an $m$-length approximate cover of $T$, if for every string $C'$ of length $m$ over $\Sigma$, $\min_{S(C') \in \Sigma^m} H(S(C'), T) \geq \min_{S(C) \in \Sigma^n} H(S(C), T)$, where $H$ is the Hamming distance of the given strings.

We refer to $\min_{S(C) \in \Sigma^n} H(S(C), T)$ as the number of errors of an $m$-length approximate cover of $T$.

**Definition 8 (Approximate Cover).** Let $T$ be a string of length $n$ over alphabet $\Sigma$. A string $C$ over alphabet $\Sigma$ is called an approximate cover of $T$ if:

1. $C$ is an $m$-length approximate cover of $T$ for some $m \in \mathbb{N}$, $m < n$, for which

$$\min_{S(C) \in \Sigma^n} H(S(C), T) = \text{dist}.$$

2. for every $m'$-length approximate cover of $T$, $C'$, s.t. $\min_{S(C') \in \Sigma^n} H(S(C'), T) = \text{dist}$, it holds that: $m' \geq m$.

**Primitivity.** By definition, an approximate cover $C$ should be primitive, i.e., it cannot be covered by a string other than itself (otherwise, $T$ has a cover with a smaller length). Note that a periodic string can be covered by a smaller string (not necessarily the period), and therefore, is not primitive.

**Definition 9.** The Approximate Cover Problem (ACP) is the following:

**INPUT:** String $T$ of length $n$ over alphabet $\Sigma$.

**OUTPUT:** An approximate cover of $T$, $C$, and the number of errors in $T$.

The goal of the following definition and lemmas is Lemma 15, which is a crucial tool for the efficiency of the candidate relaxation algorithm.

**Definition 10 (String Mask).** Given a string $C$ of length $m$, the mask $M$ of $C$ is a boolean array of length $m$, such that $M[i] = 1$ if and only if the suffix $C[i..m]$ is equal to the prefix $C[1..m-i+1]$.

**Lemma 11.** Let $C$ be a string of length $m$ and let $M$ be its mask. Let $i, j$ be indices such that $1 \leq i < j \leq m$ and $M[i] = M[j] = 1$, then the substring $C[i..m]$ has a period of length $j-i$.

**Lemma 12.** Let $C$ be a primitive string of length $m$ and let $M$ be its mask. Let $i$ be the smallest index such that $1 < i \leq m$ and $M[i] = 1$, then $i > \lfloor \frac{m}{2} \rfloor + 1$.

**Lemma 13.** Let $C$ be a string of length $m$ and let $M$ be its mask. Let $i, j$ be indices such that $M[i] = M[j] = 1$, $j-i = g > 0$. Let $k$ be the minimal index such that $j < k \leq m$ and $M[k] = 1$. Then, $k = j + g$ or $k \geq j + \lfloor \frac{g}{2} \rfloor$.

**Lemma 14.** Let $C$ be a string of length $m$ and let $M$ be its mask. Let $i, j, k, \ell$ be indices such that $i < j$, $k < \ell$, $M[i] = M[j] = M[k] = M[\ell] = 1$ and $j - i = \ell - k$ then $C[i..j-1] = C[k..\ell-1]$.  

**CPM 2017**
Lemma 15. Let $C$ be a primitive string of length $m$ and let $M$ be its mask. Let $I_M$ be the sorted list of indices $i$ such that $1 \leq i \leq m$ and $M[i] = 1$. Let $S_C = \{C[i_k,i_{k+1} - 1] \mid i_k,i_{k+1} \text{ are adjacent indices in } I_M\} \cup \{C[m] \mid m = \max_{i_k \in I_M} i_k\}$ be a set of substrings of $C$. Then, $|S_C| = O(\log m)$.

3 Characterization of the Cover Recovery Problem Approximation

In this section we study the Cover Recovery Problem (CRP) and characterize the extent to which the cover of the original unknown uncorrupted original string can be recovered given the possibly corrupted by mismatch errors input string. The term approximation here refer to the ability to give a relatively small size set of candidates that includes the exact cover of the original string or a seed of it. We begin with a formal definition of the CRP problem.

Definition 16 (The Cover Recovery Problem).

INPUT: An $\varepsilon > 0$ and a string $S'$ of length $n$ over alphabet $\Sigma$, which is a string $S$ covered by the primitive cover $C$ possibly corrupted by at most $\frac{n}{2(1+\varepsilon)c}$ mismatch errors, where $c$ is the length of $C$.

OUTPUT: A small size set $O$ of candidate strings such that $C \in O$.

First, we show the bounds on the number of errors that still guarantees a small-size set $O$ of candidates. We then prove a bound on the size of this set $O$. In Section 4 we then conclude how this set can be identified, and thus the original uncorrupted string can be approximately recovered. Some more formal definitions and lemmas are needed. We start with the definitions of alignment and neighbourhood that we use to prove the bound on the number of errors that still enable a recovery.

Remark. Throughout this section we use $c$ to denote a cover length and $C$ the cover string, i.e., $c = |C|$.

Definition 17. Let $S = S[1],\ldots,S[s]$ and $T = T[1],\ldots,T[t]$ be strings, and let $1 \leq i \leq |T|$. The alignment of $S$ with $T$ in location $i$ is the comparison of $S[j]$ and $T[i+j-1]$, $\forall j = 1,\ldots,\min(s,t-i+1)$. In other words, we place $S$ above $T$ such that the first location of $S$ is aligned with the $i$-th location of $T$.

Definition 18. Let $C = C[1],\ldots,C[c]$ be a primitive cover, and let $1 \leq i \leq c$. We call $i$ a neighbouring index of $C$ if $\forall j, j = 1,\ldots,c-i$, we have $C[i+j] = C[j]$. For any neighbouring index $i$, denote by $C_{\circ i} C$ the string composed of the prefix of length $i$ of $C$ concatenated by $C$. We call $C_{\circ i} C$ the neighbourhood of $C$ at index $i$. In particular, if $i = c$ then $C_{\circ i} C$ is $C^2$, the concatenation of $C$ with itself.

If we are interested in a neighbourhood of $C$ where the location is not important, we will denote it by $C \circ C$.

Lemma 19 is the basic building block in our error bound proof.

Lemma 19. Let $C$ be a primitive cover and $C_{\circ i} C$ be a neighbourhood of $C$ at location $i$. Then for every $j \neq i, 1 < j \leq c$, the alignment of $C$ with $C_{\circ i} C$ in location $j$ has at least one mismatch.

Proof. Because $C$ is a primitive cover, then $i > c/2$, by Lemma 12. If $1 < j \leq c/2$ then an exact alignment leads to non-primitivity of $C$, contradiction. However, if there is an exact alignment for $c/2 < j \neq i$, then $|j - i| < c/2$ and thus we again have a contradiction to the primitivity of $C$. Therefore, there must be at least one mismatch in an alignment at any index $j \neq i$. ▲
We make use of following lemma for proving the upper bound on the number of candidates in our output set.

**Lemma 20.** Let $S$ and $C$ be two primitive strings such that $C$ is a seed of $S$. Then there is at most one string $S'$ with the following properties:
1. $S'$ is covered by $C$.
2. $S$ is a substring of $S'$
3. $S'$ is the shortest string with properties 1 and 2 above.

**Proof.** Assume there are two such strings, $S'$ and $S''$. Since they are both shortest possible superstrings of $S$ (i.e., strings containing $S$ as a substring), then $S$ matches each of them in their first occurrence of $C$. If $S' \neq S''$ then there must be at least one index $i$ in $S$ where $C$ starts in $S'$ but not in $S''$. However, then by Lemma 19 there must be at least one mismatch in the alignment of at least one of them with $S$, contradiction to the fact that $S$ is a substring of both of them. ▶

**Lemma 21.** Let $n \in \mathbb{N}$ and let $S_1, S_2$ be two $n$-long coverable strings with $C_1$ and $C_2$ the covers of $S_1$ and $S_2$ respectively, where $c_1 \geq c_2$ and $C_2$ is not a seed of $C_1$. Then
\[
H(S_1, S_2) \geq \frac{n}{c_1}.
\]

We are now ready to prove our approximation bound for the CRP. Lemma 22 is needed for proving our characterization theorem.

**Lemma 22.** Let $\varepsilon > 0$ be a constant, $S$ an $n$-long string, and $C_1, C_2$ are $c_1$ and $c_2$-length approximate seeds of $S$ with at most $\frac{n}{(2 + \varepsilon) \cdot c_1}$, $\frac{n}{(2 + \varepsilon) \cdot c_2}$ errors respectively (w.l.o.g. assume that $c_1 \geq c_2$), where $C_2$ is not a seed of $C_1$. Then,
\[
c_1 \geq (1 + \varepsilon) \cdot c_2.
\]

**Proof.** Let $S_1$ be the $n$-long string such that $C_1$ is its seed and $S_2$ be the $n$-long string such that $C_2$ is its seed. We are given that $H(S_1, S) \leq \frac{n}{(2 + \varepsilon) \cdot c_1}$ and $H(S_2, S) \leq \frac{n}{(2 + \varepsilon) \cdot c_2}$. Therefore,
\[
\frac{n}{(2 + \varepsilon) \cdot c_1} + \frac{n}{(2 + \varepsilon) \cdot c_2} \geq H(S_1, S) + H(S_2, S).
\]

By triangle inequality we have,
\[
H(S_1, S) + H(S_2, S) \geq H(S_1, S_2).
\]

By Lemma 21,
\[
H(S_1, S_2) \geq \frac{n}{c_1}.
\]

Therefore,
\[
\frac{n}{(2 + \varepsilon) \cdot c_1} + \frac{n}{(2 + \varepsilon) \cdot c_2} \geq \frac{n}{c_1}
\]
from which we get,
\[
c_2 + c_1 \geq (2 + \varepsilon) c_2
\]
or,
\[
c_1 \geq (1 + \varepsilon) c_2.
\]
We conclude with our characterization theorem, which is a more accurate version of Theorem 3.

**Theorem 23.** Let $S$ be an $n$-long string. Then, there are at most $\log_{1+\varepsilon} n + 1$ different $c$-length approximate covers $C$ of $S$ with at most $\frac{n}{(2+\varepsilon)c}$ errors such that none is a seed of another.

**Proof.** First, note that there cannot be two such different $c$-length approximate covers unless one is a seed of the other, because then, by Lemma 22, we get $c \geq (1 + \varepsilon)c$, contradiction. Thus, such different $c$-length approximate covers must have different length. Now, let $1 \leq l_1 < l_2 < \ldots < l_{t-1} < l_t \leq n$ be the different lengths of $c$-length approximate covers of $S$. By Lemma 22,

$$(1 + \varepsilon)^{t-1} \leq (1 + \varepsilon)^{t-1} \cdot l_1 < (1 + \varepsilon)^{t-2} \cdot l_2 < \ldots < (1 + \varepsilon)^2 \cdot l_{t-2} < (1 + \varepsilon) \cdot l_{t-1} < l_t \leq n$$

Therefore, $t - 1 \leq \log_{1+\varepsilon} n$.

**Example 24.** We now show an example where a string has many substrings that all cover the given string with two errors. However, all these substrings have a single shortest 2-error seed. Consider the string $S = \text{aaaaaaaaa}(\text{baaaa})^k \text{baaaaaaaaa}$. Then, all the following primitive strings cover $S$ with two errors: $\text{aaaabaaaa}$, $\text{aaaabaaa}$, $\text{aaaabaa}$, $\text{aaabaa}$, $\text{aaabaaa}$, $\text{aabaaa}$, $\text{abaaa}$. They all have either $\text{abaaaa}$ or $\text{aaabaa}$ as a seed. Note that there are 2 such shortest 2-error covers, however, each is a seed of the other.

## 4 The Candidate Relaxation of the ACP

In this section we study the following relaxation of the approximate cover problem:

**Definition 25** (The Candidate Relaxation of the ACP). Input: String $T$ of length $n$ over alphabet $\Sigma$, and a candidate cover $C$ of length $m$ over alphabet $\Sigma$. Output: $\min_{S(C) \in \Sigma^n} H(S(C), T)$, i.e., the minimum number of errors in any valid tiling of $C$ in $T$.

**Remark.** If $k = \min_{S(C) \in \Sigma^n} H(S(C), T)$, we use the term $k$-error cover for the given $C$.

Note that, since a candidate cover must be primitive, we may assume that this is indeed the case. A linear-time verification is possible using the algorithm of [9]. We describe a dynamic programming algorithm for this problem, which uses the well-known Knuth-Morris-Pratt [22] and Abrahamson-Kosaraju [1] algorithms. Our algorithm consists of a preparation phase, and a dynamic programming phase. We denote by $m^*$ the number of set bits in the mask $M$ of the given candidate $C$.

### 4.1 The preparation phase

The preparation phase is composed of the following three stages:

1. **Computing the mask of $C$.** This computation can be performed efficiently using the KMP algorithm. We compute the “failure automaton” for $C$. Denote the states of the automaton by $s_0, s_1, s_2, \ldots, s_m$. We consider the final state $s_m$ of the automaton, and follow the sequence of fail links that start from it. Assume that this sequence is $s_m, s_{i_1}, s_{i_2}$, etc. The first link in the sequence means that $C_1$, the longest proper prefix of $C$ that is equal to the corresponding suffix, is of length $i_1$. The second link means that $C_2$, the
longest proper prefix of $C_1$ that is equal to the corresponding suffix of $C_1$, is of length $i_2$.
However, $C_2$ is also the second longest prefix of $C$ that is equal to the corresponding suffix of $C$.
By continuing in this process, we obtain the sequence $C_1, C_2, \ldots$ of all prefixes of $C$ that are equal to the corresponding suffixes.
Hence, the corresponding sequence of lengths $i_1, i_2, \ldots$ gives the (decreasing) sequence of indices $j_\ell = m - i_\ell + 1$, for which $M[j_\ell] = 1$, where $M$ is the mask of $C$.

2. Dividing $C$ into disjoint substrings. We divide $C$ into substrings according to the indices $i$ for which $M[i] = 1$. Specifically, if the (increasing) sequence of indices $i$ for which $M[i] = 1$ is $i_1, i_2, \ldots, i_m$ where $1 = i_1 < i_2 < \ldots < i_m$, then the substrings we consider are all substrings of $C$ of the form $s_j = C[i_j..i_{j+1} - 1]$, for $1 \leq j \leq m^* - 1$, along with the suffix $s_m = C[i_m..m]$.

3. Computing the Hamming distance from substrings of $T$ to the strings $s_j$. For each string $s_j$, $1 \leq j \leq m^*$, we compute its Hamming distance to all substrings of $T$ simultaneously using the Abrahamson-Kosaraju algorithm. Since for many values of $j$, $s_j$ is equal to $s_{j-1}$ (actually, by Lemma 15, the sequence $s_1, s_2, \ldots, s_m$, contains only $O(\log m)$ distinct elements), we first check whether $s_j = s_{j-1}$ and apply the Abrahamson-Kosaraju algorithm only in the rare cases of inequality. The array of Hamming distances returned by the Abrahamson-Kosaraju algorithm is denoted below by $\text{Hamming}(s_j, T)$.

4.2 The dynamic programming phase

When the preparation phase is done, we are ready to compute the minimal $k$ such that $C$ is a $k$-error cover of $T$. This computation is performed in a dynamic fashion. Namely, we go over all suffixes of $T$ in an increasing order, and for each suffix $T[i..n]$, we compute the minimal $k(T[i..n])$ such that $C$ is a $k(T[i..n])$-cover of $T[i..n]$, utilizing the computations performed for the previous suffixes. The values $k(T[i..n])$ are stored in an array $MIN$, where $MIN[i] = k(T[i..n])$. In the beginning of the algorithm, all values of $MIN$ are initialized to $\infty$.

As a cover must be a suffix of the covered string, we have $MIN[i] = \infty$ for all $i > n - m + 1$, meaning that there does not exist a string of length $n - i + 1$ that can be covered by $C$. For the same reason, $MIN[n - m + 1] = H(C, T[n - m + 1..n])$, as there is a unique way to cover a string of length $m$ by $C$. Since any two overlapping occurrences of $C$ in a tiling that covers the suffix $T[i..n]$ must differ by a value $j$ such that $M[j+1] = 1$, and since $s_1 = \min(j : 1 < j \leq m, M[j+1] = 1)$, it is impossible to cover a string of length $m + j$, $1 \leq j < |s_1|$, by copies of $C$. Thus, $MIN[i] = \infty$ for all $n - m - |s_1| + 1 < i < n - m + 1$.
The following steps are performed for all $i \leq n - m - |s_1|$, in a decreasing order.

For each such $i$, we go over all possible strings of length $n - i + 1$, $S_{L_i}(C)$ that cover $T[i..n]$ by $C$ with $k$-errors (resulted from different tiling $L_i$ for which its first index is aligned with index $i$ in the text). As each such tiling must start with a copy of $C$, and as the second occurrence of $C$ in this tiling must differ from the initial one either by $m$ or by a value $j$ such that $M[j+1] = 1$, we can compute the minimal number of error in any such tiled strings $S_{L_i}(C)$ (for which the first occurrence of $C$ is aligned with index $i$ in $T$ and the second occurrence of $C$ is index $j$) as $\text{Error}(S_{L_i}(C)) = H(C[1..j], T[i..i + j - 1]) + MIN[i+j]$ (note that by the structure of the algorithm, $MIN[i+j]$ is already known at this stage.)
The value $MIN[i]$ is given by:

$$MIN[i] = \min_{j \in \{j : M[j+1] = 1\} \cup \{m\}} \text{Error}(S_{L_j}(C)).$$

Naively, we can go over all $m^*$ possible values of $j$, compute $\text{Error}(S_{L_j}(C))$ for each of them, and find out the minimum. For the sake of efficiency, we compute these values incrementally,
Can We Recover the Cover?

by advancing the starting point of the second occurrence of $C$ in the covering by $|s_j|$ every time. Formally, this is performed as follows.

We define a counter $j$ that corresponds to the initial shift of the second occurrence of $C$ in the tiling relative to the position $i$ in $T$. $j$ is initialized to 0. Then, for $\ell = 1, 2, \ldots, m^*$, we advance $j$ by $|s_\ell|$ and check whether $H(C[i..j], T[i..i+j-1]) + MIN[i+j]$ for $j = \sum_{r=1}^{\ell} |s_r|$ is lower than the previously best value of Error. If the answer is positive, the temporary value of $MIN[i]$ is replaced by $H(C[i..j], T[i..i+j-1]) + MIN[i+j]$.

In order to compute the values $H(C[i..j], T[i..i+j-1])$ efficiently, we observe that for $j = \sum_{r=1}^{\ell} |s_r|$, we have

$$H(C[i..j], T[i..i+j-1]) = H(s_1, T[i..i+|s_1|-1]) + H(s_2, T[i+|s_1|..i+|s_1|+|s_2|-1]) + \ldots + H(s_\ell, T[i+\sum_{r=1}^{\ell-1} |s_r|..i+\sum_{r=1}^{\ell-1} |s_r|])$$

Hence, we compute $H(C[i..j], T[i..i+j-1])$ incrementally by keeping a counter err, initializing it to 0, and advancing it by $H(s_r, T[i+\sum_{\ell=1}^{r-1} |s_r|..i+\sum_{r=1}^{\ell-1} |s_r|])$ when $j$ is advanced by $|s_\ell|$. Finally, in order to skip unnecessary operations, for each $\ell$ we check whether $i+j+|s_\ell| \leq n-m+1$, as otherwise, an occurrence of $C$ clearly cannot start at position $i+j$.

After going over $\ell = 1, 2, \ldots, m^*$, we fix the last temporary value $MIN[i]$ to be its final value, and proceed to $i-1$. As mentioned before, $MIN[1]$ is the output of the algorithm. A pseudo-code of the algorithm is presented in Figure 1.

The correctness of the Candidate Relaxation Dynamic Programming algorithm is given in Lemma 26. The complexity of the algorithm is given in Lemma 27.

**Lemma 26.** Let $T$ be a length-$n$ string and let $C$ be a length-$m$ cover. Let $MIN$ be the final array obtained by the dynamic programming algorithm described above with input $T$ and $C$. Then for any $1 \leq i \leq n$, $MIN[i]$ is equal to the minimal $k$ such that $C$ is a $k$-error cover of $T[i..n]$.

**Proof.** The proof is by an inverse induction on $i$. The induction basis is the cases $i > n-m-|s_i|+1$, for which $MIN[i]$ was calculated explicitly above and is easily seen to be equal to their final value computed by the algorithm.

Assume that the claim holds for all $i > i_0$, and consider the case $i = i_0$. Let $S_{L_{i_0}}(C)$ be the tiled string of $T[i_0..n]$ by copies of $C$ starting from index $i_0$, for which the minimal number of errors $k(T[i_0..n])$ is attained. The tiling $S_{L_{i_0}}(C)$ must start with a copy of $C$, and the second occurrence of $C$ in $S_{L_{i_0}}(C)$ must differ from the initial one either by $m$ or by a value $j$ such that $M[j+1] = 1$. As the total error of $S_{L_{i_0}}(C)$ is $k(T[i_0..n])$, we have

$$k(T[i_0..n]) \geq H(C[i..j], T[i..i_0+j-1]) + k(T[i_0+j..n])$$

On the other hand, by the structure of our algorithm, its outputs satisfy

$$MIN[i] \leq H(C[i..j], T[i..i_0+j-1])+MIN[i_0+j] = H(C[i..j], T[i..i_0+j-1]+k(T[i_0+j..n]))$$

where the equality holds by the induction assumption. Hence, $MIN[i_0] \leq k(T[i_0..n])$. Finally, since $MIN[i]$ is obtained in the algorithm by computing the error of a concrete cover (that can be traced inductively), it is clear that $MIN[i] \geq k(T[i_0..n])$. This completes the proof. ▶

17. \( j \leftarrow 0 \)
18. \( \text{err} \leftarrow 0 \)
19. for each substring \( s_\ell \) do
20. if \( j + |s_\ell| \leq n - m \) then
21. \( \text{err} \leftarrow \text{err} + \text{Hamming}(s_\ell, T[i + j]) \)
22. if \( \text{MIN}[i] > \text{err} + \text{MIN}[i + j + |s_\ell|] \) then
23. \( \text{MIN}[i] \leftarrow \text{err} + \text{MIN}[i + j + |s_\ell|] \)
24. \( j \leftarrow j + |s_\ell| \)

**Output:**

25. \( \text{MIN}[1] \)

Figure 1 The dynamic programming algorithm for the candidate relaxation of the ACP.

Lemma 27. Let \( T \) be a text of length \( n \) and \( C \) a candidate cover of length \( m \). Then, the time complexity of the Candidate Relaxation Dynamic Programming algorithm on \( T \) and \( C \) is \( O(n \cdot m^* + n\sqrt{m \log m}) \), where \( m^* \) is the number of set bits in the mask \( M \) of \( C \).

Proof. First, we analyze the preparation phase of the algorithm. As explained above in the description of the algorithm, computing the mask \( M \) of \( C \) can be done by running the KMP algorithm for \( C \), which requires \( O(m) \) operations. Dividing \( C \) into disjoint substrings given the mask \( M \) of \( C \) clearly can be done in \( O(m) \) operations. Computing the Hamming distance from substrings of \( T \) to the strings \( s_j \) can be performed by applying the Abrahamson-Kosaraju algorithm once for each of the substrings \( s_j \). As by Lemma 15, the number of distinct substrings \( s_j \) is \( O(\log m) \), the Abrahamson-Kosaraju algorithm is applied only \( O(\log m) \) times, while for the other values of \( j \) (whose total number is bounded from above by \( m \)) we perform only a simple “copy” operation. The complexity of each application of the Abrahamson-Kosaraju algorithm is \( O(n\sqrt{m \log m}) \), and hence, the total complexity of this step is \( O(n\sqrt{m \log m}) \).

A refinement of the analysis of this computation shows that the complexity is actually \( O(n\sqrt{m \log m}) \). Note that the Abrahamson-Kosaraju algorithm is applied for distinct strings of the form \( s_j \). Consider the lengths of these strings. By Lemma 15, if we denote \( |s_k| = g_k \) and let \( h_k \) denote the distance from the end of \( s_k \) to the end of \( C \), we have that whenever
Can We Recover the Cover?

$s_{k+1} \neq s_k$, or $g_{k+1} \leq g_k/2$ or $h_{k+1} \leq 3h_k/4$. Moreover, as the latter condition arises only in the case $h_k \leq 2g_k$ (see the proof of Lemma 15), it follows that the sequence of lengths $g_1 > g_2 > \ldots$ of strings on which the Abrahamson-Kosaraju algorithm is applied satisfies $g_{k+1} < g_k/4$. Since $g_1 \leq m$, the total complexity of this step is at most $O(n\sqrt{m \log m})$.

We now analyze the dynamic programming phase. The main loop of the dynamic programming is performed for all $1 \leq i \leq n - m - |s_1|$, i.e., $O(n)$ times. For each $i$, we go over the $m^*$ strings $s_j$, and for each of them, we perform a few simple operations (i.e., table lookups and comparisons). Hence, the time complexity of this phase is $O(n \cdot m^*)$.

Therefore, the total time complexity of the algorithm is $O(n \cdot m^* + n\sqrt{m \log m})$.

This completes the proof of Theorem 28.

**Theorem 28.** Given a text $T$ of length $n$ a candidate cover $C$ of length $m$ over alphabet $\Sigma$. Then, the candidate relaxation of the approximate cover problem of $T$ can be solved in $O(n \cdot m^* + n\sqrt{m \log m})$ time, where $m^*$ is the number of set bits in the mask $M$ of $C$.

Theorem 28 has the following useful applications to the ACP (Corollary 29) and CRP (Corollary 30).

**Corollary 29.** Let $T$ be a text of length $n$ over alphabet $\Sigma$. Denote by $\gamma(T)$ the maximum of $m^* + \sqrt{m \log m}$ over all primitive substrings $C$ of $T$ with length $m < n$, where $m^*$ is the number of set bits in the mask $M$ of $C$. Assume that the error distribution guarantees that at least one occurrence of an approximate cover of the text is without errors. Then, the approximate cover problem of $T$ can be solved in $O(n^3 \cdot \gamma(T))$ time.

**Proof.** The condition implies that $C$ is a substring of $T$. Take each of the $O(n^2)$ primitive substrings of $T$ of length less than $n$ as a candidate cover in the algorithm and run the dynamic programming algorithm of Figure 1. The corollary then follows from Theorem 28.

**Corollary 30.** Let $S$ be a $n$-long string and $\epsilon > 0$. Denote by $\gamma(S)$ the maximum of $m^* + \sqrt{m \log m}$ over all primitive substrings $C$ of $S$ with length $m < n$, where $m^*$ is the number of set bits in the mask $M$ of $C$. Then, a set of at most $\log_2 \frac{1+\epsilon}{\epsilon} n$ different $m$-length approximate covers $C$ of $S$ such that none is a seed of another, each with at most $\frac{n}{(2+\epsilon) m}$ errors, can be constructed in $O(n^3 \cdot \gamma(S))$ time.

**Proof.** Use the same algorithm as in the proof of Corollary 29 but retain as candidates in the output set only $m$-length approximate covers $C$ of $S$, for which the candidate relaxation algorithm finds at most $\frac{n}{(2+\epsilon) m}$ errors. From this set retain only candidates that do not have a shorter or same length candidates as seeds.

## Open Problems

In this paper we initiated the study of the CRP as well as a new relaxation of the ACP. Some interesting questions and open problems are:

- Since the ACP is proved to be $\mathcal{NP}$-hard, it is interesting to find other polynomial time relaxations of the ACP, besides the candidate relaxation studied in this paper. Such a study will broaden our understanding as well as suggest practical solutions.

- In this paper we considered the Hamming distance as a metric in the definition of approximate cover. Other string metrics can be considered as well. It is interesting to see if and how the complexity of the problem changes with the use of other string metrics.

Abstract

Regularities in strings arise in various areas of science, including coding and automata theory, formal language theory, combinatorics, molecular biology and many others. A common notion to describe regularity in a string \( T \) is a cover, which is a string \( C \) for which every letter of \( T \) lies within some occurrence of \( C \). The alignment of the cover repetitions in the given text is called a tiling. In many applications finding exact repetitions is not sufficient, due to the presence of errors. In this paper, we use a new approach for handling errors in coverable phenomena and define the approximate cover problem (ACP), in which we are given a text that is a sequence of some cover repetitions with possible mismatch errors, and we seek a string that covers the text with the minimum number of errors. We first show that the ACP is \( \mathcal{NP} \)-hard, by studying the cover-size relaxation of the ACP, in which the requested size of the approximate cover is also given with the input string. We show this relaxation is already \( \mathcal{NP} \)-hard. We also study another two relaxations of the ACP, which we call the partial-tiling relaxation of the ACP and the full-tiling relaxation of the ACP, in which a tiling of the requested cover is also given with the input string. A given full tiling retains all the occurrences of the cover before the errors, while in a partial tiling there can be additional occurrences of the cover that are not marked by the tiling. We show that the partial-tiling relaxation has a polynomial time complexity and give experimental evidence that the full-tiling also has polynomial time complexity. The study of these relaxations, besides shedding another light on the complexity of the ACP, also involves a deep understanding of the properties of covers, yielding some key lemmas and observations that may be helpful for a future study of regularities in the presence of errors.

1 Introduction

Regularities in strings arise in various areas of science, including coding and automata theory, formal language theory, combinatorics, molecular biology and many others. A typical form of regularity is periodicity, meaning that a “long” string \( T \) can be represented as a concatenation of copies of a “short” string \( P \), possibly ending in a prefix of \( P \). Periodicity has been extensively studied in Computer Science over the years (see [26]).
For many phenomena, it is desirable to broaden the definition of periodicity and study wider classes of repetitive patterns in strings. One common such notion is that of a cover, defined as follows.

**Definition 1 (Cover).** A length $m$ substring $C$ of a string $T$ of length $n$, is said to be a cover of $T$, if $n > m$ and every letter of $T$ lies within some occurrence of $C$.

Note that by the definition of cover, the string $C$ is both a prefix and a suffix of the string $T$. For example, consider the string $T = \text{abaababaaba}$. Clearly, $T$ is “almost” periodic with period $\text{aba}$, however, as it is not completely periodic, the algorithms that exploit repetitions cannot be applied to it. On the other hand, the string $C = \text{aba}$ is a cover of $T$, which allows applying to $T$ cover-based algorithms. In this paper we study coverable phenomena in the presence of errors.

There are related regularity types and several approaches to handle errors in regularities. Quasi-periodicity was introduced by Ehrenfeucht in 1990 (according to [5]). The earliest paper in which it was studied is by Apostolico, Farach and Iliopoulos [7], which defined the quasi-period of a string to be the length of its shortest cover and presented an algorithm for computing the quasi-period of a given string in $O(n)$ time and space. The new notion attracted immediately several groups of researchers (e.g. [8], [27, 28], [25], [9]). An overview on the first decade of the research on covers can be found in the surveys [5, 19, 30].

While covers are a significant generalization of the notion of periods as formalizing regularities in strings, they are still restrictive, in the sense that it remains unlikely that an arbitrary string has a cover shorter than the word itself. Due to this reason, different variants of quasi-periodicity have been introduced. These include *seeds* [18], *maximal quasi-periodic substring* [6], the notion of *k-covers* [20], *λ-cover* [31], *enhanced covers* [15], *partial cover* [21]. Other recently explored directions include the inverse problem for cover arrays [13], extensions to strings in which not all letters are uniquely defined, such as *indeterminate strings* [4] or *weighted sequences* [32]. Some of the related problems are *NP*-hard (see e.g., [4, 10, 21]).

In applications such as molecular biology and computer-assisted music analysis, finding exact repetitions and covers is not always sufficient. A more appropriate notion is that of approximate repetitions, where errors are allowed (see, e.g., [12, 14]). This notion was first studied in 1993 by Landau and Schmidt [23, 24] who concentrated on approximate tandem repeats. Note that, the natural definition of an approximate repetition is not clear. One possible definition is that the distance between any two adjacent repeats is small. Another possibility is that all repeats lie at a small distance from a single “original”. Such a definition of approximate seeds is studied in [10, 17, 16]. Indeed, all these definitions along with other ones were proposed and studied (see [1, 22, 29]). Yet another possibility is that all repeats must be equal, but we allow a fixed total number of mismatches. The possibility presented in [1] is a global one, assuming that an original unknown string is a sequence of repeats without errors, but the process of sequence creation or transmission incurs errors to the sequence of repeats, and, thus, the examined input string is not a sequence of repeats. Therefore, a (smallest) repeat generating a string with the minimum total number of mismatches with the input string is sought. Extension of this definition approach to approximate covers is the topic of this paper.

### 1.1 Our Results

In this paper we extend the approach of [1] to the notion of covers and define the approximate cover problem (ACP), in which we are given a text that is a sequence of some cover repetitions with possible mismatch errors, and we seek a string that covers the text with the minimum
number of errors. The alignment of the cover repetitions in the given text is called a tiling. We prove that the ACP is $\mathcal{NP}$-hard by studying a relaxation of this problem, which we call the cover-size relaxation of the ACP. In this relaxation the requested size of the approximate cover is also given with the input string. We prove that this relaxation is already $\mathcal{NP}$-hard, thus proving the $\mathcal{NP}$-hardness of ACP.

We also study another two relaxations of the problem, which we call the partial-tiling relaxation of the ACP and the full-tiling relaxation of the ACP. In this relaxations a tiling of the requested cover is also given, and we seek a string such that when using the given tiling to align it with the given text, the number of mismatches is minimized. The full tiling retains all the occurrences of the cover before the errors, while in the partial tiling there can be additional occurrences of the cover that are not marked by the tiling. We examine these relaxations and show the partial-tiling has polynomial time complexity and give experimental evidence that the full-tiling also has polynomial time complexity. The study of these relaxations, besides shedding another light on the complexity of the ACP, also involves a deep understanding of the properties of covers and seeds, yielding some key lemmas and observations (such as [2]) that may be helpful for a future study of regularities in the presence of errors.

Paper Contributions. The main contributions of this paper are:

- Proving that the ACP is $\mathcal{NP}$-hard.
- Formalizing the partial-tiling relaxation of the ACP and proving it is polynomial time computable.
- Formalizing the full-tiling relaxation of the ACP and suggesting a polynomial time algorithm for its computation, while giving an experimental evidence for the correctness of this algorithm.

The paper is organized as follows. In Section 2, we give formal definitions. In Section 3, we study the cover-size relaxation of the ACP and prove the $\mathcal{NP}$-hardness of the ACP. In Section 4, we study the partial-tiling relaxation of the ACP and show it is polynomial-time computable. In Section 5, we study the full-tiling relaxation of the ACP, suggest a polynomial-time algorithm for this problem and experimentally test its correctness. We conclude with some open problems in Section 6.

2 Preliminaries

In this section we give the needed formal definitions.

Definition 2 (Tiling). Let $T$ be a string over alphabet $\Sigma$ such that the string $C$ over alphabet $\Sigma$ is a cover of $T$. Then, the sorted list of indices representing the start positions of occurrences of the cover $C$ in the text $T$ is called the tiling of $C$ in $T$.

In this paper we have a text $T$ which may have been introduced to errors and, therefore, is not coverable. However, we would like to refer to a retained tiling of an unknown string $C$ in $T$ although $C$ does not cover $T$ because of mismatch positions. The following definition makes a distinction between a list of indices that may be assumed to be a tiling of the text before mismatch errors occurred and a list of indices that cannot be such a tiling.

Definition 3 (A Valid Tiling). Let $T$ be an $n$-length string over alphabet $\Sigma$ and let $L$ be a sorted list of indices $L \subset \{1, \ldots, n\}$. Let $m = n + 1 - L_{\text{last}}$, where $L_{\text{last}}$ is the last index in $L$. Then, $L$ is called a valid tiling of $T$, if $i_1 = 1$ and for every $i_k, i_{k+1} \in L$, it holds that $i_{k+1} - i_k \leq m$.
Approximate Cover of Strings

► **Notation 1.** Let $C$ be an $m$-length string over alphabet $\Sigma$. Denote by $S(C)$ a string of length $n$, $n > m$, such that $C$ is a cover of $S(C)$.

Note that $S(C)$ is not uniquely defined even for a fixed $n > m$, since every different valid tiling of the $m$-length string $C$ generates a different $n$-length string $S(C)$. A unique version can be obtained if a valid tiling $L$ is also given.

► **Notation 2.** Let $T$ be an $n$-length string over alphabet $\Sigma$ and let $L$ be a valid tiling of $T$. Let $m = n + 1 - L_{\text{last}}$, where $L_{\text{last}}$ is the last index in the tiling $L$. For any $m$-length string $C'$, let $S_L(C')$ be the $n$-length string obtained using $C'$ as a cover and $L$ as the tiling as follows: $S_L(C')$ begins with a copy of $C'$ and for each index $i$ in $L$ a new copy of $C'$ is concatenated starting from index $i$ of $S_L(C')$ (maybe running over a suffix of the last copy of $C'$).

► **Definition 4.** Let $T$ be a string of length $n$ over alphabet $\Sigma$. Let $H$ be the Hamming distance. The distance of $T$ from being covered is:

$$\text{dist} = \min_{C \in \Sigma^*, |C| < n, S(C) \in \Sigma^n} H(S(C), T).$$

We will also refer to $\text{dist}$ as the number of errors in $T$.

► **Definition 5.** Let $T$ be an $n$-long string over alphabet $\Sigma$. An $m$-long string $C$ over $\Sigma$, $m \in \mathbb{N}$, $m < n$, is called an $m$-length approximate cover of $T$, if for every string $C'$ of length $m$ over $\Sigma$, $\min_{S(C') \in \Sigma^n} H(S(C'), T) \geq \min_{S(C) \in \Sigma^n} H(S(C), T)$, where $H$ is the hamming distance of the given strings.

We refer to $\min_{S(C) \in \Sigma^n} H(S(C), T)$ as the number of errors of an $m$-length approximate cover of $T$.

► **Definition 6 (Approximate Cover).** Let $T$ be a string of length $n$ over alphabet $\Sigma$. A string $C$ over alphabet $\Sigma$ is called an approximate cover of $T$ if:

1. $C$ is an $m$-length approximate cover of $T$ for some $m \in \mathbb{N}$, $m < n$, for which

$$\min_{S(C) \in \Sigma^n} H(S(C), T) = \text{dist}.$$

2. for every $m'$-length approximate cover of $T$, $C'$, s.t. $\min_{S(C') \in \Sigma^n} H(S(C'), T) = \text{dist}$, it holds that: $m' \geq m$.

**Primitivity.** By definition, an approximate cover $C$ should be primitive, i.e., it cannot be covered by a string other than itself (otherwise, $T$ has a cover with a smaller length). Note that a periodic string can be covered by a smaller string (not necessarily the period), and therefore, is not primitive.

► **Definition 7.** The Approximate Cover Problem (ACP) is the following:

- **INPUT:** String $T$ of length $n$ over alphabet $\Sigma$.
- **OUTPUT:** An approximate cover of $T$, $C$, and the number of errors in $T$.

## 3 \mathcal{NP} \text{-Hardness of the ACP}

In this section we prove the \mathcal{NP}-hardness of the ACP. To this end, we study a variant of the problem where $m$, the length of a requested approximate cover, is also given together with the input string $T$, and we are requested to find a string $C$ of length $m$ that is an
m-length approximate cover of \( T \), i.e., \( C \) covers \( T \) with the minimum number of errors over all strings of length \( m \). We call this problem the cover-size relaxation of the ACP. Clearly, if the cover-size relaxation of the ACP is already \( \mathcal{NP} \)-hard, then so is the ACP.

Our hardness proof uses a reduction from the 3-SAT problem, in which the input is a logical formula \( \phi \) on \( N \) variables in 3-CNF (each clause has exactly three literals), and we need to decide whether \( \phi \) is satisfiable or not. The \( \mathcal{NP} \)-hardness of 3-SAT is well-known (see e.g. [11]).

3.1 The Reduction from 3-SAT

Given a 3-CNF formula \( \phi \) on \( N \) variables, \( x_1, \ldots, x_N \), with \( \ell \) clauses. Assume without loss of generality that the literals in each clause are sorted by the index of their variables. We need to define a text \( T \) of length \( n \) over an alphabet \( \Sigma \) and to specify the size \( m \) of the requested approximate cover. We will then show that \( \phi \) is satisfiable if and only if \( T \) has an \( m \)-approximate cover with at most some specified number of errors to be defined.

We begin by defining the alphabet \( \Sigma \) to include all the variables and their negation together with 4 additional dummy variables: \( x_0, x_{-1}, x_{N+1}, x_{N+2} \) and also a special padding character \( p \). Formally,

\[
\Sigma = \{ x_i, \bar{x}_i | i \in [1..N] \} \cup \{ x_{-1}, x_0, x_{N+1}, x_{N+2}, p \}.
\]

The definition of the text \( T \) has two parts: a header and a body, where the body of \( T \) is defined according to the clauses of the given logical formula \( \phi \), and the header preceding this body imposes a structure on an \( m \)-approximate cover for \( T \).

The definition of the body of \( T \) follows directly from the formula \( \phi \). For each clause \( C_j = L_{j1} \lor L_{j2} \lor L_{j3} \) of \( \phi \), \( 1 \leq j \leq \ell \), we add to the body of \( T \) the substring \( L_{j1}L_{j2}L_{j3} \), preceded and followed by a padding of \( 2N + 14 \) occurrences of the character \( p \). The role of this padding is to avoid overlaps between occurrences of an approximate cover covering substrings originating from different clauses. The header is composed of \( \ell(N+3) \) copies of the following string: \( \bar{B} = p \ldots px_{N+2}x_{N+1}x_N \ldots x_{1}x_0x_{-1}p \ldots px_{N+2}x_{N+1}x_N \ldots x_{1}x_0x_{-1}p \ldots p \), where each padding contains \( N + 7 \) occurrences of \( p \).

We define the size of the requested approximate cover \( m \) to be \( 3N + 18 \). Note that the size of \( T \) and \( m \) as well as their construction are polynomial in \( N \) and \( \ell \). Lemma 8 assures the correctness of the reduction.

\textbf{Lemma 8.} \( \phi \) is satisfiable if and only if \( T \) has an \( m \)-approximate cover with at most \( \ell(N+3)(N+1) \) errors.

We have, therefore, proven Theorem 9.

\textbf{Theorem 9.} ACP is \( \mathcal{NP} \)-hard.

4 The Partial-Tiling Relaxation of the ACP

In this section we study another relaxation of the approximate cover problem: the partial-tiling relaxation, in which we are given a retained tiling of the cover before the errors has occurred together with the input string itself. In order to formally define the relaxation we need Definitions 10 and 11.

\textbf{Definition 10.} Let \( T \) be an \( n \)-length string over alphabet \( \Sigma \) and let \( L \) be a valid tiling of \( T \). Let \( m = n + 1 - L_{last} \), where \( L_{last} \) is the last index in the tiling \( L \). Then, an
Approximate Cover of Strings

**L-approximate cover of T** is a primitive string $C$ such that for every string $C'$ of length $m$ over $Σ$, $H(S_L(C'), T) ≥ H(S_L(C), T)$, where $H$ is the hamming distance of the given strings. $\min_{C∈Σ^m} H(S_L(C), T)$ is the number of errors of an $L$ approximate cover of $T$.

**Definition 11.** Let $T$ be an $n$-length string over alphabet $Σ$. Let $L$ be a valid tiling of $T$ and let $L'$ be a valid tiling of $T$ such that $L ⊆ L'$. Let $m' = n + 1 - L'_{last}$, where $L'_{last}$ is the last index in the tiling $L'$. Then, a **partial $L$-approximate cover** of $T$ is a primitive string $C$ of length $m'$ such that for every string $C'$ of length $m'$ over $Σ$, $H(S_L(C'), T) ≥ H(S_L(C), T)$, where $H$ is the hamming distance of the given strings. $\min_{C∈Σ^m} H(S_L(C), T)$ is the number of errors of a partial $L$-approximate cover of $T$.

**Definition 12 (The Partial-Tiling Relaxation of the ACP).**

**INPUT:** String $T$ of length $n$ over alphabet $Σ$, and a valid tiling $L$ of $T$.

**OUTPUT:** A partial $L$-approximate cover $C$ of $T$.

We describe an algorithm for the partial-tiling relaxation of the approximate cover problem in two parts. We first describe the mandatory part of the algorithm, which we call the Histogram Greedy Algorithm. This algorithm does the main work in finding an approximate cover subject to the tiling $L$. It returns a candidate for the final $L$ approximate cover to be output. This candidate is legal if it is primitive and illegal, otherwise. We then describe the second part, which we call the Partial-Tiling Primitivity Coercion. In this part, the legality of the candidate is checked, and if needed, the candidate is corrected in order to coerce the primitivity requirement.

### 4.1 The Histogram Greedy Algorithm

This part of the algorithm performs the following steps given the text $T$ and the valid tiling $L$:

1. Find $m$, the length of an approximate cover subject to the tiling $L$, by computing the difference between $n + 1$, and the last index in the tiling $L$, $L_{last}$, which indicates the last occurrence of the cover in $T$.

2. Compute the $m$-length mask $M$ of an approximate cover, by initializing $M$ to zeroes, setting $M[1] = 1$, then reading the tiling $L$ from beginning to end and for each $i_k$, $i_{k+1} ∈ L$ setting $M[i_{k+1} - i_k] = 1$.

3. Compute the $m$-long string $VC$ of variables from an auxiliary alphabet $Σ_V = \{v_1, v_2, ..., v_m\}$.

First, we initialize the $m$-long string $VC$ to $v_1v_2...v_m$. Then, we read the mask $M$ from end to beginning, and for every $j$ such that $M[j] = 1$, we update the string $VC$ by equalizing the substrings $VC[1..m - j + 1]$ and $VC[j..m]$. In the equalization process, when we obtain an equation $v_k = v_ℓ$ for $k < ℓ$, the resulting string $VC$ represents $C$ in the following sense: for any pair of indices $1 ≤ i < j ≤ m$, if $VC[i] = C[j]$ then $C[i] = C[j]$. However, it can be that $VC[i] ≠ C[j]$, while $C[i] = C[j]$. In other words, $VC$ carries the information on equalities imposed by the mask $M$ between indices of $C$.

4. Compute the $n$-long string $VT$ of variables from the auxiliary alphabet $Σ_V$, which is a string covered by $VC$ according to the tiling $L$ of $T$. $VC$ is computed using the tiling $L$ and $VC$ as follows: it begins with a copy of $VC$ and for each index $i$ in $L$ a new copy of $VC$ is concatenated starting from index $i$ of $VT$ (maybe running over a suffix of the last copy of $VC$).
5. Compute the histogram $Hist_{V_C,\Sigma}$ using the alignment of $T$ with $V_T$ and counting for each variable $V \in V_C$ and each $\sigma \in \Sigma$, the number of indices $i$ in $T, V_T$ for which $V_T[i] = V$ and $T[i] = \sigma$.

6. Compute an $L$ approximate cover candidate $C$ greedily according to the histogram $Hist_{V_C,\Sigma}$, as follows: for every index $1 \leq i \leq m$, set $C[i] = \sigma_0$, where $Hist_{V_C,\Sigma}[V_C[i], \sigma_0] = \max_{\sigma \in \Sigma} Hist_{V_C,\Sigma}[V_C[i], \sigma]$, i.e., for each index in $C$ we choose the alphabet symbol that minimizes the number of mismatch errors between $S_L(C)$ and $T$ in the relevant indices according to the tiling $L$.

The algorithm outputs the $m$-length string $C$ from its last step and the histogram table $Hist_{V_C,\Sigma}$.

Lemma 13 describes a property of the output $C$ returned by the Histogram Greedy algorithm, and immediately follows from the greedy criterion used in step 6 of the algorithm. Lemma 14 describes the algorithm time complexity.

**Lemma 13.** Let $C$ be the output of the Histogram Greedy algorithm. Then,

$$H(T, S_L(C)) = \min_{C' \in \Sigma^m} H(T, S_L(C'))$$

**Lemma 14.** The time complexity of the Histogram Greedy algorithm is: $O(|\Sigma| \cdot m + n)$.

Despite Lemma 13, the output $C$ of the Histogram Greedy algorithm might not be an $L$ approximate cover of $T$, because it might not be primitive, as the following example shows.

**Example:** Assume that $V_C = XYZWXY$ and $\Sigma = \{a, b\}$ and that the histogram $Hist_{V_C,\Sigma}$ computed by the algorithm is the following:

<table>
<thead>
<tr>
<th>$V_C \setminus \Sigma$</th>
<th>a</th>
<th>b</th>
</tr>
</thead>
<tbody>
<tr>
<td>X</td>
<td>4</td>
<td>1</td>
</tr>
<tr>
<td>Y</td>
<td>2</td>
<td>3</td>
</tr>
<tr>
<td>Z</td>
<td>2</td>
<td>1</td>
</tr>
<tr>
<td>W</td>
<td>0</td>
<td>3</td>
</tr>
</tbody>
</table>

Then, the Histogram Greedy algorithm chooses: $X = a$, $Y = b$, $Z = a$, $W = b$, and outputs $C = ababab$, which cannot be considered a legal cover since it is not primitive, i.e., $C$ itself can be covered by the shorter string $ab$. However, the partial $L$-approximate cover can have a tiling $L'$, such that $L \subseteq L'$, which exactly is the case with $ab$. Therefore, $ab$ should be returned as the partial $L$-approximate cover of $T$. The Partial-Tiling Primitivity Coercion algorithm described in Subsection 4.2 is responsible for checking the legality of the output string received from the Histogram Greedy algorithm and returning a partial $L$-approximate cover.

Note, that the input tiling $L$ requires an $m$-length string as an output. Therefore, the (primitive) 2-length approximate cover $ab$ is precluded as an $L$-approximate cover. Assuming that the input tiling $L$ is the retained tiling of the cover of the original text before the errors occurred, such a case means that, though $ab$ is a string covering $T$ subject to a partial tiling $L$ with the least number of errors, it does not cover $T$ with $L$ as a full tiling. In this sense, $L$ is an evidence that the original cover is of larger length than $ab$ and that more errors actually happened. Section 5 is devoted to finding an $L$-approximate cover.

### 4.2 The Partial-Tiling Primitivity Coercion Algorithm

This part of the algorithm gets as input the string $C$ returned by the Histogram Greedy algorithm and performs the following steps:
1. Check the primitivity of \( C \) (using the linear-time algorithm of [7]). If \( C \) is primitive, return \( C \).

2. Else, return the primitive cover \( C' \) of \( C \) (found using the linear-time algorithm of [7] in the first step).

The time complexity of the Partial-Tiling Primitivity Coercion algorithm is immediate from the linear-time complexity of the algorithm in [7]. Thus, we get:

\[ \text{Lemma 15. The time complexity of the Partial-Tiling Primitivity Coercion algorithm is } O(m). \]

Theorem 16 follows.

\[ \text{Theorem 16. Given a text } T \text{ of length } n \text{ over alphabet } \Sigma \text{ and a valid tiling } L. \text{ Let } L_{\text{last}} \text{ be the last index in } L. \text{ Then, the partial-tiling relaxation of the approximate cover problem of } T \text{ can be solved in } O(|\Sigma| \cdot (m + n)) \text{ time, where } m = n + 1 - L_{\text{last}}. \]

5 The Full-Tiling Relaxation of the ACP

In this section we study another relaxation of the approximate cover problem: the full-tiling relaxation, in which we are given a retained tiling of the cover before the errors have occurred together with the input string itself. Unlike the situation in the problem of the previous section, this tiling is assumed to be exact. Therefore, the algorithm cannot return as cover a string that in order to cover \( T \) must have repetitions that are not marked in the tiling \( L \).

The formal definition of the problem is as follows:

\[ \text{Definition 17 (The Full-Tiling Relaxation of the ACP).} \]

\[ \text{INPUT: String } T \text{ of length } n \text{ over alphabet } \Sigma, \text{ and a valid tiling } L \text{ of } T. \]

\[ \text{OUTPUT: An } L \text{-approximate cover } C \text{ of } T. \]

In order to impose the requirement of the definition of an \( L \)-approximate cover of \( T \) to be a primitive string such that all its repetitions to cover \( T \) (with minimum number of errors) are marked in the tiling \( L \), we need a different primitivity coercion algorithm than the one described in the previous section. This algorithm is described in Subsection 5.1. Unfortunately, proving the correctness of this algorithm requires a deep understanding of the properties of coverability in the presence of mismatch errors. Although we are making progress in proving this needed background (see, for example [2]), a lack in the complete understanding of the phenomenon prevents us from proving the correctness formally. Hence, in Subsection 5.2, we resort to experimental evidence of the correctness.

5.1 The Full-Tiling Primitivity Coercion Algorithm

This part of the algorithm gets as input the string \( C \) returned by the Histogram Greedy algorithm (Subsection 4.1) and performs the following steps:

1. Check the primitivity of \( C \) (using the linear-time algorithm of [7]). If \( C \) is primitive, return \( C \).

2. Else, find \( V_k \in V_C \) such that if the assignment of \( V_k \) is changed from the symbol with the largest value in the row of \( V_k \) in \( \text{Hist}_{V_C, \Sigma} \) to the symbol with the second largest value in this row, thus obtaining a new \( m \)-length candidate string \( C' \), such that the difference \( H(S_L(C'), T) - H(S_L(C), T) \) is minimized and where \( C' \) is primitive.

Lemma 18. The time complexity of the Full-Tiling Primitivity Coercion algorithm is $O(|\Sigma| \cdot m)$.

Remark: Note that we can use a different algorithm that instead of checking the change of single variables to the second best assignment and choosing the one that gives primitivity with the least number of errors (as our algorithm does), checks the changing to the second best assignment of all subsets of variables and chooses the set that gives primitivity with the least number of errors. This algorithm is obviously correct, i.e., assures primitivity with the least number of errors, however, it has an exponential-time complexity. On the other hand, our algorithm is assured to have polynomial-time complexity, so a proof of its correctness will assure the polynomial-time complexity of the full-tiling relaxation of the ACP.

5.2 Experimental Tests of the Full-Tiling Relaxation Algorithm

Experiment were designed to test the full-tiling relaxation algorithm, which is composed of the algorithms of Subsections 4.1 and 5.1. In particular, we also wanted to experimentally test how many times the full-tiling primitivity coercion is necessary. Note that, due to the result of [3], this algorithm is only of interest to test under a rather high error rate, in which there is an error in every occurrence of the approximate cover of the text, otherwise, the dynamic programming algorithm solving the candidate-relaxation of the ACP is applicable, where trying every substring of $T$ as a candidate cover [3]. In order to comprehensively test the algorithm, the inputs for the tests were classified according to the following criteria:

- **cover size:** A cover $C$ of size $m$ is constructed, where $m$ is small (less than 10), medium (10-100) or large (100-400). Covers of size more than 400 were not created due to space limitations.

- **alphabet size:** The alphabet size was chosen to be either small (at most $\sqrt{m}$) or large (more than $\sqrt{m}$).

- **tiling style:** Given a cover $C$ and its mask $M$, a tiling $L$ for the text $S_L(C)$ is constructed where the decision of the next index in $L$ is made according to the following styles: random – an equal priority is given to every set bit in $M$, left priority – a decreasing priority is given to the set bits in $M$, right priority – an increasing priority is given to the set bits in $M$.

- **error rate:** The input string $T$ is constructed from $S_L(C)$ by inserting mismatch errors according the following error rates: medium (in every $m$ characters at least one error), high (in every $m$ characters at least $\sqrt{m}$ errors).

- **error style:** The mismatching character is determined according to the following style: random (replacing by a uniformly at random choice of another character from the alphabet) or priority (replacing by another character with priority to the first character in the alphabet, and if the first character is to be replaced then by a uniformly at random chosen different character).

These criteria guarantee that the inputs created for testing the algorithm all have a coverable original string, that its valid tiling is retained. This original string is then introduced with a sufficiently high error rate to produce the current string together with the valid tiling as inputs for the tiling relaxation algorithm. Therefore, all the tested inputs have an $L$ approximate
Approximate Cover of Strings

cover and our tiling relaxation algorithm is indeed applicable for them. Moreover, the above criteria for input generation also aim at neutralizing the effect of the cover size, the alphabet size, the tiling style, the error rate or the error style on the validity of the hypothesis, by exhaustively using all reasonable alternatives.

A total of 372,000 texts \( T \) were constructed as described above and served as inputs (together with the tiling \( L \)) to the full-tiling relaxation algorithm. The results are given in Tables 1 and 2 (see Appendix). The column “Percent of Inputs” describes how many of the input texts had each row’s characteristics. Numbers are rounded to two digits after decimal point. The column “Identical” describes in how many of the input texts the Histogram Greedy algorithm of Subsection 4.1 returned the original cover \( C \) of the text \( S_L(C) \) built prior to the error insertion process. The column “Primitive” describes in how many of the input texts the Histogram Greedy algorithm of Subsection 4.1 returned a primitive cover and there was no need to proceed with the second phase of the Full-Tiling Primitivity Coercion algorithm of Subsection 5.1. The column “Non-Primitive” describes in how many of the input texts the Histogram Greedy algorithm of Subsection 4.1 returned a non-primitive string and, therefore, the second phase of the Full-Tiling Primitivity Coercion algorithm of Subsection 5.1 was performed. This latter case happened in 8,912 texts, which are about 2% of the texts.

Experiments Conclusion: Primitivity coercion was necessary in 2% of the total tested inputs. In a 100% of the tests the returned string after the Full-Tiling Primitivity Coercion algorithm was indeed an \( L \)-approximate cover of the input string.

6 Open Problems

In this paper we initiated the study of the approximate cover problem using a new approach. We proved that the some relaxations (the cover size relaxation) of the approximate cover problem are \( \mathcal{NP} \)-hard, thus proving that the ACP is \( \mathcal{NP} \)-hard, while other relaxations (the partial-tiling relaxation and the full-tiling relaxation) are polynomial-time computable. Some interesting questions and open problems are:

- Our \( \mathcal{NP} \)-hardness proof uses unbounded-size alphabet. Is the ACP still \( \mathcal{NP} \)-hard for finite alphabet?
- It is interesting to define other relaxations of the ACP and to study their complexity in order to have a deeper understanding of the ACP.
- In this paper we only experimentally checked the correctness of our full-tiling relaxation algorithm. We would like to have a formal proof of its correctness.
- In this paper we considered the Hamming distance as a metric in the definition of approximate cover. Other string metrics can be considered as well. It is interesting to see if and how the complexity of the problem changes with the use of other string metrics.

Beyond Adjacency Maximization: Scaffold Filling for New String Distances

Abstract

In Genomic Scaffold Filling, one aims at polishing in silico a draft genome, called scaffold. The scaffold is given in the form of an ordered set of gene sequences, called contigs. This is done by confronting the scaffold to an already complete reference genome from a close species. More precisely, given a scaffold $S$, a reference genome $G$ and a score function $f()$ between two genomes, the aim is to complete $S$ by adding the missing genes from $G$ so that the obtained complete genome $S^*$ optimizes $f(S^*, G)$. In this paper, we extend a model of Jiang et al. [CPM 2016] (i) by allowing the insertions of strings instead of single characters (i.e., some groups of genes may be forced to be inserted together) and (ii) by considering two alternative score functions: the first generalizes the notion of common adjacencies by maximizing the number of common k-mers between $S^*$ and $G$ (k-Mer Scaffold Filling), the second aims at minimizing the number of breakpoints between $S^*$ and $G$ (Min-Breakpoint Scaffold Filling). We study these problems from the parameterized complexity point of view, providing fixed-parameter (FPT) algorithms for both problems. In particular, we show that k-Mer Scaffold Filling is FPT wrt. parameter $\ell$, the number of additional k-mers realized by the completion of $S$—this answers an open question of Jiang et al. [CPM 2016]. We also show that Min-Breakpoint Scaffold Filling is FPT wrt. a parameter combining the number of missing genes, the number of gene repetitions and the target distance.

Introduction

The recent development and continuous improvement of NGS technologies has increased our ability to produce, rapidly and inexpensively, a first draft of any genome. However, the cost of polishing such drafts to obtain a complete genome has not decreased at the same rate, thus many species are left with a genome in its scaffold form: a scaffold may be represented as a sequence of contigs (each being a contiguous sequence of genes), separated by unknown

A visit from Laurent Bulteau and Christian Komusiewicz which initiated this study was funded by PEPS INS2I from CNRS and Internationalisation des Laboratoires – Action 1 from Université de Nantes.
gaps, sometimes with an indication on the length of the gap. It is thus natural to ask for methods that reconstruct the complete original genome starting from its scaffold form. This is usually done with the help of a reference genome $G$, that is, the complete genome of a close-enough species, in the following way: turn the scaffold $S$ into a complete genome $S^*$ by adding, in between the contigs of $S$, genes that are present in $G$ but not in $S$, in such a way that some predefined score function based on $S^*$ and $G$ is optimized. The score function is usually defined so as to follow the parsimony principle: when $S^*$ and $G$ are as close as possible, the score is optimized.

Formally, a genome $G$ is a string built on some alphabet $\Sigma$ (each character in the alphabet representing a gene or gene family), and a scaffold $S$ is defined as sequence $(C_1, \ldots, C_m)$ of contigs, where each $C_i$, $1 \leq i \leq m$, is itself a string over $\Sigma$. For a string $S$ of length $n$, we let $c(S)$ be the multiset of characters it contains, and $a(S) := \{S[i, i + 1] \mid i \in [n - 1]\}$ be the multiset of adjacencies in $S$. By extension, if $S$ is a scaffold, $c(S)$ (resp. $a(S)$) denotes the multiset of characters (resp. adjacencies) contained in the contigs of $S$. For two strings $S$ and $T$, let $a(S,T) := a(S) \cap a(T)$ denote the multiset of common adjacencies in $S$ and $T$. For a scaffold $S$ and a multiset $T$ of strings, we use $S + T$ to denote the set of strings that can be obtained from $S$ by inserting the strings of $T$ in between the contigs of $S$. The \textsc{One-Sided-Scaffold-Filling} problem, introduced in [13], was the first serious attempt at modeling scaffolds as a sequence of contigs with repeats.

\textsc{One-Sided-Scaffold-Filling}

\textbf{Input:} A complete genome $G$ and a scaffold $S=(C_1, \ldots, C_m)$ over alphabet $\Sigma$, and a multiset $T = c(G) - c(S)$ of characters.

\textbf{Task:} Find $S^* \in S + T$ s.t. $\|a(S^*, G)\|$ is maximized.

Note that Jiang et al. [13] also considered the variant in which only a subset $T' \subseteq T$ of the letters of $T$ needs to be inserted. In this paper, we study two alternative problems.

\textbf{k-Mer Scaffold Filling.} The first one generalizes both of the problems considered by Jiang et al. [13] in several ways. First, we do not constrain the multiset of letters to insert to be $c(G) - c(S)$. Instead, the set $T$ could contain letters in higher or lower multiplicity than in $c(G) - c(S)$. This is helpful if it is known, for example, that some genes occur in higher multiplicity in the desired genome than in $G$. Second, we allow that $T$ contains strings instead of only letters. This allows to incorporate knowledge about the gene order that is not present in the tuple of scaffold contigs. For example, one may now deal with contigs whose position relative to the other contigs is not known. Third, we allow that the number of strings to insert can be prespecified as an input constraint. More precisely, in our variant the input contains two numbers $t_1$, $t_2$, and we search for a solution that inserts at least $t_1$ and at most $t_2$ strings from $T$. This way, one can guarantee for example that the size of the resulting genome lies within some predetermined range. If we want all of $T$ to be inserted in $S$, it suffices to set $t_1 := |T| := t_2$. The second variant of Jiang et al. [13] in which an arbitrary subset of $T$ may be inserted is obtained by setting $t_1 := 1$ and $t_2 := |T|$.

Finally, as similarity measurement we do not restrict ourselves to maximizing the number of common adjacencies. Instead, we maximize, for a predetermined parameter $k$, the number of common $k$-mers (the term $k$-mer is usually used for DNA strings; we thus extend its use here in the context of gene sequences): indeed, as illustrated in Figure 1, a higher value of $k$ tends to increase the accuracy of the result.

For a string $S$ of length $n$ and a positive integer $k$, let $a_k(S) := \{S[i, i + k] \mid i \in [n-k]\}$ denote the multiset of $k$-mers in $S$. For two strings $S$ and $T$, $a_k(S,T) := a_k(S) \cap a_k(T)$
We are now ready to define our second problem, which is also illustrated in Figure 2. In that case, just as in permutations, breakpoints are defined as the dual of\( \text{strings instead of only letters. Second, instead of maximizing the number of common Scaffold Filling.} \)

The second problem we study here differs from Min-Breakpoint Scaffold Filling.\( \text{event (by swapping factors aabca and abcb).} \)

denotes the multiset of common \( k \)-mers in \( S \) and \( T \). Note that counting common adjacencies is the special case \( k = 2 \). The problem we are interested in is thus defined as follows (see Figure 1 for an illustration with \( k = 2 \) and \( k = 3 \)).

\( k \)-Mer Scaffold Filling (\( k \)-Mer-SF)

\textbf{Input:} A complete genome \( G \) and a scaffold \( S \) of contigs \( (C_1, \ldots, C_m) \) over alphabet \( \Sigma \), a multiset \( T \) of strings over \( \Sigma \) and integers, \( t_1, t_2 \) s.t. \( t_1 \leq t_2 \leq |T| \).

\textbf{Task:} Find \( T' \subseteq T \), \( t_1 \leq |T'| \leq t_2 \), and \( S^* \in S + T' \) s.t. \(|a_k(S^*, G)|\) is maximized.

Min-Breakpoint Scaffold Filling. The second problem we study here differs from One-Sided-Scaffold-Filling in two ways: first, just as \( k \)-Mer-SF, we allow that \( T \) contains strings instead of only letters. Second, instead of maximizing the number of common adjacencies, we aim at minimizing the number of breakpoints. We need additional definitions: given two strings \( S \) and \( T \) such that \( c(S) = c(T) \), thus of same length \( n \), and a bijection \( \pi : [n] \to [n] \) such that \( S[i] = T[\pi(i)] \), the breakpoint distance wrt. \( \pi \) between \( S \) and \( T \) is \(|\{i \mid \pi(i + 1) \neq \pi(i), 1 \leq i < n\}|\). The string breakpoint distance between \( S \) and \( T \), denoted \( b(S, T) \), is the minimum over all bijections \( \pi \) of the breakpoint distance of \( S \) and \( T \) wrt. \( \pi \). We are now ready to define our second problem, which is also illustrated in Figure 2.

\textbf{Min-Breakpoint Scaffold Filling (Min-Bkpt-SF)}

\textbf{Input:} A complete genome \( G \) and a scaffold \( S \) over alphabet \( \Sigma \) and a multiset \( T \) of strings over \( \Sigma \).

\textbf{Task:} Find \( S^* \in S + T \) s.t. \( b(S^*, G) \) is minimized.

Note that there exists attempts at defining breakpoints in strings in the context of scaffold filling [15, 16]. In that case, just as in permutations, breakpoints are defined as the dual of common adjacencies. This differs from the present definition: in our case, there exist strings
Beyond Adjacency Maximization: Scaffold Filling for New String Distances

Figure 2: Left: an example instance of MIN-BKPT-SF, with scaffold $S$ containing 4 contigs, $T$ containing 4 strings of length 1 and 2 to be inserted, and a reference genome $G$. An optimal solution inserts the strings from $T$ as indicated by dashed arcs to create $S^*$. Right: the resulting string $S^*$ is at breakpoint distance 3 from $G$: the letters of $S$ and $G$ can be matched together to form 4 common blocks (hence $4 - 1 = 3$ breakpoints).

$S$ and $T$ of length $n$ such that $a(S,T) + b(S,T) = n + k$ with $k = \Omega(n)$. Moreover, our definition of breakpoints is of particular interest when $S$ and $T$ are very close: for instance, the number of common adjacencies cannot discriminate the case $S = T$ from $S \neq T$ (take e.g. $S = \text{aabbab}$ and $T = \text{abaabb}$), whereas our definition of breakpoints does, and even allows to estimate how $S$ differs from $T$.

Finally, note that following the motivation in genomic scaffolding, we demand that no insertions are made before $C_1$ or after $C_m$. This variant is more general than the one where insertions are allowed everywhere since we can simply add two additional contigs which have letters not occurring in $G$, one in the beginning and one in the end. Then, there is always an optimal solution that does not insert before the first or after the last contig.

$k$-MER-SF and MIN-BKPT-SF are studied here from the parameterized (or multivariate) complexity point of view [5, 8, 10]. The main parameters that will be used in the following are: $k$, the length of the $k$-mers; $\ell := a_k(S^*, G) - a_k(S, G)$, the number of additional common $k$-mers brought by completion; $d$, the duplication number, that is, the maximum number of times a letter appears in $G$; $m$, the number of contigs in $S$; $t_2$, the upper bound on number of letters to insert; $\lambda$, an upper bound on the length of the strings in $T$; $b = b(S^*, G)$, the sought breakpoint distance.

Related work and our contribution. Genomic Scaffold Filling (GSF) has been introduced by Muñoz et al. [20] in 2010. The problem has initially been defined for permutations, i.e. genomes are modeled as duplication-free sequences. Under this setting, GSF is polynomial-time solvable for the DCJ distance [20] and for maximizing the number of adjacencies [16, 19] (or, equivalently, minimizing the breakpoint distance). This method has been validated through simulations and the comparison of two plant genomes [20].

When scaffolds are modeled as strings (thus allowing gene repetitions), it becomes harder to compute relevant parsimony measures, hence almost all works are concerned with maximizing the number of common adjacencies. In many cases with this model, the “contig” constraint has been lifted, so that a scaffold has been modeled as a simple string, and insertion can be done between any pair of consecutive letters. For GSF, Jiang et al. [17, 16] showed the problem to be NP-hard, and from then on several approximation algorithms have been given – the best to date achieves a ratio of 1.2 [14]. Buliu et al. [3] showed that GSF is FPT in the sought number of adjacencies $\ell$.

More recently, as in this paper, scaffolds were considered to be a sequence $(C_1, \ldots, C_m)$ of contigs. Jiang et al. [13] considered GSF under this model, again with the maximum adjacency measure. They proved the problem to be NP-hard even if only two contigs are given, gave a 2-approximation for the problem, and showed the problem to be FPT.
We extend the definition of functions in a natural way to work with multiset domains. That is, a function \( f \) wrt. the combined parameter \( \ell \), the number of sought common adjacencies, and \( d \), the duplication number. A short survey of the most recent results concerning GSF under the maximum adjacency setting can be found in [21]. In particular, the following question was raised [13, 21]: what is the FPT status of the problem when the parameter is the number of adjacencies?

In this paper, we study \( k\text{-Mer-SF} \) and \( \text{MIN-Bkpt-SF} \) from a parameterized complexity point of view. In particular, we show that \( k\text{-Mer-SF} \) is \( W[1]\)-hard wrt. parameter \( t_2 \), and FPT wrt. parameter \( \ell \), thereby answering the above open question positively. We also provide a polynomial kernel for the parameter \( \ell + m \) for the case where \( t_2 = |T| \), \( \lambda = 1 \) and \( k = 2 \), which corresponds to earlier definitions of the GSF problem. Concerning \( \text{MIN-Bkpt-SF} \), we provide hardness results even in some restricted cases (e.g. when \( b = 0 \) and \( m = 2 \)), and we provide several FPT results wrt. combinations of some of the input parameters.

**Preliminaries.** For a string \( S \), we use \( S[i] \) to denote the letter at position \( i \) and \( S[i,j] \) to denote the substring starting at position \( i \) and ending at position \( j \); if \( i > j \), then \( S[i,j] \) is defined as the empty string. We use \( S_k[i] := S[i, i + k - 1] \) to denote the length-\( k \) substring of \( S \) starting at position \( i \). For two strings \( S \) and \( T \) we denote the concatenation of \( S \) and \( T \) by \( S \cdot T \). For a multiset or tuple of strings \( S \), we use \(|S|\) to denote the sum of the lengths of the strings contained in \( S \). We use \([n] := \{1, \ldots, n\}\) to denote the numbers from 1 through \( n \).

For a multiset \( X \) over a universe \( U \) and an element \( u \) of \( U \), let \( m(X, u) \) denote the multiplicity of \( u \) in \( X \). If \( m(X, u) \geq 1 \), then we write \( x \in X \), if \( m(X, u) = 0 \), then we write \( u \not\in X \).

We extend the definition of functions in a natural way to work with multiset domains. That is, a function \( f : X \to Y \) with \( X \) a multiset is defined as a function \( f_S : S_X \to Y \) where \( S_X := \{(x, i) : x \in X, i \in [m(X, x)]\} \) is a set containing, for each \( x \in X \), \( m(X, x) \) many different elements corresponding to \( x \). We write \( f(x) := \{f_S((x, i)) : i \in [m(X, x)]\} \) to denote the set of images of \( x \). Throughout the paper, \( n := |G| \) will denote the length of the input genome \( G \) both in \( k\text{-Mer-SF} \) and \( \text{MIN-Bkpt-SF} \).

For the relevant definitions of parameterized complexity theory, refer to [8, 10].

## 2 The Relation between \( k\)-Mer Scaffold Filling and Partial Set Cover

In the following, we describe a reduction from the following variant of Set Cover to \( k\text{-Mer-SF} \).

**Partial Set Cover**

**Input:** A family \( \mathcal{F} = \{F_1, \ldots, F_m\} \) of subsets of a universe \( U = \{u_1, \ldots, u_n\} \) and integers \( \kappa \) and \( \tau \).

**Task:** Find a subfamily \( \mathcal{F}' \subseteq \mathcal{F} \) of size at most \( \kappa \) such that \( |\bigcup_{F_i \in \mathcal{F}'} F_i| \geq \tau \).

On the positive side, Partial Set Cover can be solved in \((2e)^\tau \cdot |U| \cdot |F| \) time [2]. For the parameter \( \kappa \), however, Partial Set Cover is \( W[1]\)-hard [12].

**Lemma 1.** For each \( k \geq 2 \), there is a polynomial-time reduction from Partial Set Cover to \( k\text{-Mer-SF} \) such that \( t_2 = \kappa \) and \(|G| = O(n)\).

**Proof.** Given an instance of Partial Set Cover, construct an instance of \( k\text{-Mer-SF} \) for \( k = 2 \) as follows. For each \( u_i \), introduce two letters \( a_i \) and \( b_i \) and introduce a further letter \( x \). Now let \( G \) be the string \( a_1b_1xa_2b_2x\cdots xa_n b_n \). Observe that each element in \( U \) corresponds to exactly one adjacency in \( G \).
Now, for each $F_i \in F$, construct a string $T_i$ and add it to $T$. The string $T_i$ contains the substring $a_ib_j$ for each $u_j \in F_i$. More precisely, if $F_i = \{u^i_1, \ldots, u^i_t\}$, then $T_i = a^i_1b^i_1 \cdots a^i_tb^i_t$. Now add two contigs $C_1 = C_2 = y$ to the scaffold $S$ and set $t_1 = 0$ and $t_2 = \kappa$. This concludes the construction of the $k$-MER-SF instance. It remains to show the correctness of the reduction, that is,

$$(F, \kappa, \tau) \text{ is a yes-instance of } \text{PARTIAL SET COVER} \iff \text{there is a solution } S^* \text{ of } (G, S, T, 0, \kappa) \text{ for k-MER-SF such that } |a_k(S^*, G)| \geq \tau.$$

$(\Rightarrow)$ Let $F'$ be a solution of PARTIAL SET COVER. Then, for each $F_i \in F'$, insert the string $T_i$ in $S$ (in arbitrary order) and denote the resulting string by $S^*$. Since the scaffold $S$ contains no letters from $G$, all adjacencies of $G$ are missing in $S$. Let $U'$ denote the elements that are covered by $F'$. For each $u_j \in U'$, there is some $F_i$ containing $u_j$ and thus some $T_i$ containing the adjacency $a_jb_j$ which is an adjacency of $G$. Thus, $S^*$ contains at least $|U'|$ many adjacencies.

$(\Leftarrow)$ Let $S^*$ be a solution such that $|a_k(S^*, G)| \geq \tau$. Observe that every common adjacency of $S^*$ and $G$ is of the form $a_jb_j$, since all other adjacencies of $G$ contain the letter $x$. Since each adjacency is of the form $a_jb_j$, there are thus at least $\tau$ distinct indices $j$ such that $S^*$ contains the adjacency $a_jb_j$. Moreover, every such adjacency is contained in some $T_i \in T'$. By construction of $T$, $u_j$ is contained in the set $F_i$. Therefore, the set $F' := \{F_i \mid T_i \in T'\}$ covers at least $\tau$ elements of $U$. Since $T' \leq \kappa$, there are thus at most $\kappa$ sets in $F$ that cover at least $\tau$ elements of $U$.

To obtain the reduction for arbitrary $k > 2$, one may adapt the construction by representing each $u_j$ by a string of length $k$.

Corollary 1 directly implies the following hardness result for the parameter $t_2$ that bounds the number of strings to insert.

**Corollary 2.** For each $k \geq 2$, $k$-MER-SF is $W[1]$-hard with respect to the parameter $t_2$.

Next, observe that PARTIAL SET COVER is a special case of SET COVER. This implies that PARTIAL SET COVER does not admit a polynomial kernel with respect to $|U| + \kappa$ unless $\text{coNP} \subseteq \text{NP}/\text{poly}$ [9]. Together with Lemma 1 and the facts that the decision version of $k$-MER-SF is contained in NP and that SET COVER is NP-complete, we thus obtain the following.

**Corollary 3.** For each $k \geq 2$, $k$-MER-SF does not admit a kernel with respect to $|G| + \lambda + t_2$ unless $\text{coNP} \subseteq \text{NP}/\text{poly}$.

### 3 A Fixed-Parameter Algorithm for $k$-Mer Scaffold Filling

We now show how to solve $k$-MER-SF in $2^{O(t)} \cdot n^{O(1)}$ time. Let $p_k(S, G) := a_k(G) \setminus a_k(S)$ denote the multiset of $k$-mers that is in $G$ but not in the scaffold $S$. We call these the potential common $k$-mers. Also, for a solution $S^*$ we will call the common $k$-mers of $S^*$ and $G$ that are not $k$-mers of $S$ the realized $k$-mers. The algorithm that we describe is based on a combination of dynamic programming and color-coding [1]. It has running time $O(n^2 \cdot m \cdot k^3 \cdot \ell \cdot |T| \cdot 8.16^\ell \cdot 5.44^{t_2})$. Thus, it is a fixed-parameter algorithm for the combined parameter $\ell + t_2$. As the following reduction rules show, this also gives a fixed-parameter algorithm for the parameter $k + \ell$.

**Reduction Rule 1.** If $t_1 > k \cdot \ell + 1$, then set $t_1 = k \cdot \ell + 1$. If $t_2 > k \cdot \ell + 1$, then set $t_2 = k \cdot \ell + 1$. 

We will call these the potential common $k$-mers.
Proof of Correctness. First, consider the change of $t_1$. The reduction rule decreases the value of the lower bound $t_1$ for $|\mathcal{T}'|$. Thus, every feasible solution for the original instance is a feasible solution for the reduced instance that realizes the same number of common $k$-mers. To show correctness, we must thus only show that for every feasible solution of the reduced instance, there is a feasible solution of the original instance that realizes the same number of common $k$-mers. To this end, let $\mathcal{T}^*$ be an optimal feasible solution of the new instance and let $S^*$ denote the resulting string. Let $K := a_k(S^*, G) \setminus (a_k(S) \cup a_k(G))$ denote the multiset of potential common $k$-mers that are realized by $S^*$. By definition of $\ell$, we have $\ell = |K|$. Consider an injective mapping from $K$ to the $k$-mers in $S^*$ that contain at least one position from an inserted string $T \in \mathcal{T}^*$. Observe that the total number of positions in these $k$-mers of $S^*$ is at most $k \cdot \ell$. By pigeonhole principle, there is thus at least one string $T \in \mathcal{T}^*$ such that none of the $k$-mers containing $T$ is an image of the mapping. Now obtain a solution for the original instance by adding $t_2 - (k \cdot \ell + 1)$ strings from $\mathcal{T} \setminus \mathcal{T}^*$ directly after $T$. This does not affect any $k$-mers that are images of the mapping. Thus, the number of realized $k$-mers does not decrease, and the decrease of $t_1$ is correct.

Next, consider the case that the rule increases the value of the upper bound $t_2$ for $|\mathcal{T}'|$. Thus, every feasible solution for the reduced instance is a feasible solution for the original instance that realizes the same number of common $k$-mers. To show correctness, we must thus show that for every feasible solution of the original instance, there is a feasible solution of the reduced instance that realizes the same number of common $k$-mers. To this end, let $\mathcal{T}'$ be an optimal feasible solution of the original instance and assume that $\mathcal{T}'$ is the smallest among all optimal solutions. If $|\mathcal{T}'| \leq k \cdot \ell + 1$, then $\mathcal{T}'$ gives also a feasible solution for the reduced instance. Otherwise, as in the proof for the reduction of $t_1$, there is at least one string $T \in \mathcal{T}'$ such that none of the $k$-mers containing $T$ is an image of the mapping from the realized $k$-mers. Now obtain a solution for the original instance by removing $T$. This does not affect any $k$-mers that are images of the mapping. Thus, the number of realized $k$-mers does not decrease. Moreover, since $t_1 \leq k \cdot \ell + 1$, $|\mathcal{T}' \setminus \{T\}| \geq t_1$. Thus, $|\mathcal{T}' \setminus \{T\}|$ is a feasible solution for the original instance which contradicts the assumption that $\mathcal{T}'$ is the smallest such solution.

Color Coding. Somewhat deviating from the standard color-coding, we use two random colorings $\alpha$ and $\beta$. Here, $\alpha : p_k(S, G) \to [\ell]$ is a coloring of the potential common $k$-mers and $\beta : \mathcal{T} \to [t_2]$ is a coloring of the strings that may be inserted. The idea is that there is a significant chance for the two random colorings that all of the realized common $k$-mers and inserted strings have different colors. Under this assumption, we can use dynamic programming on $S$ to reconstruct a solution that realizes $\ell$ of the potential common $k$-mers.

Dynamic Programming. In the dynamic programming routine, we gradually find partial solutions of increasing size, inserting strings from $\mathcal{T}$ into the scaffold in a left-to-right manner. That is, we first insert between the first and second contig, then between the second and third and so on. We use the coloring to avoid inserting some string of $\mathcal{T}$ twice. We fill a five-dimensional table $Q[i, j, k, A, B]$ with 0/1-entries corresponding to partial solutions. In this table:
- the index $i \in [m]$ corresponds to the set of contigs that precede the last character that was inserted,
- the indices $j \in |G|$ and $k \in \{0, \ldots, k\}$ are used to identify the longest common suffix between the partial solution and $G$, 

CPM 2017
the color sets $A \subseteq [\ell]$ and $B \subseteq [t_2]$ denote the colors of the $k$-mers that were realized and the colors of the strings that were inserted.

We define the meaning of table $Q$ as follows. A table entry $Q[i, j, \kappa, A, B] = 1$ if and only if there is a set $p' \subseteq p_b(S, G)$ and a set $T' \subseteq T$ such that

1. $\alpha(p') = A$ and $|p'| = |A|$,
2. $\beta(T') = B$ and $|T'| = |B|$,
3. there is a string $S^* \in S_i + T'$ such that $a(S^*, G) \setminus a(S, G) \subseteq p'$ and $G_{\kappa}[j]$ is the longest common substring of $G$ that is a suffix of $S^*$, among all substrings of length at most $k$ of $G$.

Here, $S_i := (C_1, \ldots, C_i)$ denotes the scaffold consisting of the first $i$ contigs in the same order as in $S$ and $G_{\kappa}[j]$ denotes the length-$\kappa$ substring of $G$ starting at position $j$. Before we describe the recurrence in detail, consider the following. When extending a partial solution $S^*$, we have two choices: either add a string from $T$ at the end of $S^*$ or add the next contig, that is, add $C_i$ if the last contig in $S^*$ is $C_{i-1}$. The resulting string contains additional $k$-mers as substrings and some of these $k$-mers may be potential common $k$-mers with $G$. Clearly, to determine the set of additional $k$-mers it suffices to know the length-$k$ suffix of $S^*$ and the string that we add. The number of different length-$k$ suffixes, however, is $|\Sigma|^k$. Therefore, storing these in a dynamic programming table would incur a substantial overhead for both running time and space consumption. To be more efficient, we make use of the following fact.

Fact 1. Let $S$, $T$ and $G$ be strings such that the longest substring of $S$ that is a suffix of $G$ has length at most $\kappa$, and let $S' = (S \circ T)[i, j]$ be a substring of $S \circ T$ such that $i \leq |S|$ and $j > |S|$. If $S'$ is a substring of $G$, then $i \geq |S| - \kappa$.

Hence, the set of additional common $k$-mers of $S^* \circ T$ and $G$ are completely determined by the combination of $T$ and the longest suffix of $S^*$ that is also a substring of $G$. Finally, the additional realized $k$-mers are those that are not yet realized by $S^*$. For our dynamic programming table, we are thus interested in the $k$-mers that have a certain color set. To determine the possible contribution of adding a string $T$ we use a table $P[j, \kappa, A, T]$. An entry $P[j, \kappa, A, T]$ of $P$ has value 1 if there is a surjective mapping

$$
\psi : a_k(G_{\kappa}[j] \circ T, G) \to A
$$

from the multiset of common $k$-mers of $G_{\kappa}[j] \circ T$ and $G$ to the color set $A \subseteq [\ell]$ such that $\psi(x) \subseteq \alpha(x)$ for all $x \in a_k(G_{\kappa}[j] \circ T, G)$. Otherwise, the entry has value 0. Informally, the table $P$ tells us whether adding $T$ to a partial solution helps to realize potential $k$-mers with the colors of $A$. If we add a contig $C_i$, then we may count only those common $k$-mers that are not completely contained in $C_i$. Accordingly, the entries $P[j, \kappa, A, C_i]$ have value 1 if there is a surjective mapping

$$
\psi : (a_k(G_{\kappa}[j] \circ C_{i+1}, G) \setminus a_k(C_i)) \to A
$$

such that $\psi(x) \subseteq \alpha(x)$ for all $x \in a_k(G_{\kappa}[j] \circ T, G) \setminus a_k(C_i)$.

Lemma 4. The value of each entry of $P$ can be computed in $O(k \cdot |T| + |T| \cdot |A|^2)$ time if the multiset of $k$-mers of $G$ is stored in a trie.

Proof. First, in $O(k + |T|)$ time, compute the string $T' = G_{\kappa}[j] \circ T$. Then compute the multiset $a_k(T', G)$ of common $k$-mers of $T'$ and $G$. This can be done in $O(k \cdot |T|)$ time: the number of $k$-mers in $T'$ is at most $|T|$ and for each $k$-mer, we may use the trie to
check whether it is in \( G \) and to count the number of \( k \)-mers of \( T' \) that are equivalent. The multiset of common \( k \)-mers is then given by determining for each \( k \)-mer, the minimum of the multiplicities in \( T' \) and in \( G \).

Now, we can determine whether there is a mapping \( \psi \) by computing a maximum matching in the graph that is defined by the restriction of \( \alpha \) to \( a_k(T', G) \), that is, the bipartite graph constructed as follows: For each \( k \)-mer \( K \) of \( a_k(T', G) \) we introduce \( m(a_k(T', G), K) \) vertices corresponding to \( K \); this gives one part \( V_{\ell} \) of the bipartition. The other part of the bipartition is given by \( A \). We draw an edge between \( v \in V_{\ell} \) and \( u \in A \) if \( v \in \alpha(K_v) \), where \( K_v \) is the \( k \)-mer corresponding to \( v \). Then we compute a maximum matching in this graph. Since this matching has at most \( |A| \) edges and since the graph has size \( O(|T| \cdot |A|) \), this can be done in time \( O(|T| \cdot |A|^2) \). If every vertex of \( A \) is contained in a matching edge, then the table entry is set to 1, otherwise it is 0.

With the table \( P \) at hand, we use the following recurrence to fill \( Q \). Informally, the table entry has value 1 if some string \( T \) or the next contig \( C_i \) can be used, together with a previous partial solution, to realize common \( k \)-mers of the desired colors and if the resulting partial solution has a suffix as specified by the values of \( j \) and \( \kappa \).

\[
Q[i, j, \kappa, A, B] = \begin{cases} 
1 & \exists j', \kappa', A' \subseteq A, T \in T : \\
& Q[i, j', \kappa', A', B \setminus \beta(T)] = 1 \land \\
& P[j', \kappa', A \setminus A', T] = 1 \land \\
& G_\kappa[j] = \text{len}(G(G_\kappa[j'] \circ T)) \\
0 & \text{otherwise.}
\end{cases}
\]

Here, for two strings \( S \) and \( T \) we use \( \text{len}(S, T) \) to denote the longest substring of \( S \) that is a suffix of length at most \( k \) of \( T \).

\textbf{Theorem 5.} \( k \)-MER-SF can be solved in \( O(n^2 \cdot m \cdot k^2 \cdot |T| \cdot 8.16^t \cdot 5.44^{t^2}) \) time.

\textbf{Proof.} The overall number of entries in \( P \) is \( O(n \cdot k \cdot |T| \cdot 2^{t^2}) \). Each entry of \( P \) can be computed in \( O(k \cdot |T| + |T| \cdot |A|^2) \) time by Lemma 4. This gives an overall running time of \( O(n \cdot k^2 \cdot |T| \cdot 2^{t^2} \cdot (t_2)^2) \) for filling \( P \). The overall number of entries in \( Q \) is \( O(m \cdot n \cdot k \cdot 2^t \cdot 2^{t^2}) \). For each entry \( Q[i, j, \kappa, A, B] \), we consider \( O(n \cdot k \cdot 2^{|A|} \cdot |T|) \) cases in the recurrence. The first two conditions of each case can be determined in \( O(1) \) time, the third condition can be computed in \( O(1) \) time after a preprocessing in which we compute \( \text{len}(G(G_\kappa[j] \circ T)) \) for each combination of \( T, \kappa \) and \( j \). This can be done in \( O(n^2 \cdot k \cdot |T|) \) time overall. Thus, the total running time for filling \( Q \) including preprocessing is \( O(n^2 \cdot m \cdot k^2 \cdot |T| \cdot 3^t \cdot 2^{t^2}) \). After \( Q \) is filled, we can determine whether there is a solution realizing \( t \) potential common \( k \)-mers by considering \( Q[m, j, \kappa, \ell, B] \) for all \( B \) with \( t_1 \leq |B| \leq t_2 \). The overall running time of the algorithm now follows from the number of trials that are necessary to obtain a constant false-negative error probability, as shown by Alon et al. [1], these are exactly \( e^{t_1 + t_2} \) many.

\textbf{Corollary 6.} \( k \)-MER-SF can be solved in \( O(n^2 \cdot m \cdot k^2 \cdot |T| \cdot 8.16^t \cdot 5.44^{kt}) \) time.
4 A Polynomial Kernel for a Special Case

As an additional result, we obtain a polynomial problem kernel for the special case when \( t_2 \geq 2\ell + 1 \), \( \lambda = 1 \) and \( k = 2 \) and the parameter is the combination of \( \ell \) and \( m \). Observe that \( t_2 \geq 2\ell + 1 \) essentially means that there are no upper-bound constraints on the solution size. Thus, our kernel also works for the natural case that \( t_2 = |T| \). The details are given in Appendix. Moreover, observe that even though the problem setting is very restricted compared to the general \( k \)-MER SCAFFOLD FILLING, it contains the GSF problem of Jiang et al. [13] as a special case.

▶ Theorem 7. For \( k = 2 \), \( \lambda = 1 \) and \( t_2 \geq 2\ell + 1 \), \( k \)-MER-SF admits a problem kernel of size \( O(\ell^3 \cdot (\ell + m)^2) \) that can be computed in polynomial time.

5 Minimizing the Number of Breakpoints

In this section, we consider the Min-Bkpt-SF problem. Another formulation of the string breakpoint distance between \( S \) and \( T \) is via minimum common string partitions [7]. Intuitively, the breakpoint distance is \( b \) if the strings \( S \) and \( T \) can each be partitioned into \( b + 1 \) factors, so that both partitions use the same multiset of factors. For example, strings \( aabda \) and \( beada \) have a breakpoint distance of 2 since they can both be partitioned into the size-three factor set \( \{aa, be, da\} \) (see also Figure 2 for another example). This distance is NP-hard to compute [11], however, several FPT algorithms can be used. We will make use of the following two:

- An FPT algorithm for the parameter combining \( b \), the breakpoint distance, and \( d \), the number of duplications of any letter [4];
- An FPT algorithm for parameter \( b \) alone [6] (which is mainly of theoretical interest, as the exponential running time on \( b \) is rather prohibitive).

We first give two NP-hardness results, each one using a different approach giving different constraints on the values of the parameters. We then introduce two FPT algorithms using \( |T| \) as a parameter (as well as the breakpoint distance \( b \), and either the number of contigs \( m \) or the duplication number \( d \)). Without parameter \( |T| \), we show that the problem is in XP for parameter \( b \) when all strings in \( T \) have length 1.

NP-hardness for \( |T| = 0 \), \( m = 1 \), and either \( d = 2 \) or \( |\Sigma| = 2 \). The first hardness result below directly follows from the fact that the string breakpoint distance is hard to compute. Hence, any parameterized algorithm needs to put some restriction on the target distance \( b \).

▶ Theorem 8. Min-Bkpt-SF is NP-hard with \( |T| = 0 \), \( m = 1 \) even when either \( d = 2 \) or \( |\Sigma| = 2 \).

Proof. With an empty set \( T \) and a single contig \( C_1 \), Min-Bkpt-SF comes down to computing the breakpoint distance between two strings. It is NP-hard even in special cases of binary alphabet [18], as well as when any letter occurs at most twice [11].

NP-hardness for \( m = 2 \) and \( b = 0 \). When \( b = 0 \), we look for a way of inserting strings of \( T \) in \( S \) in order to obtain exactly \( G \). This problem turns out to be NP-hard, hence, again, any parameterized algorithm needs not only to put a bound on the the target distance \( b \), but also some restriction on the set of missing strings.
Theorem 9. MIN-BKPT-SF is NP-hard even when \( m = 2 \) and \( b = 0 \).

Proof. We propose a reduction from UNARY BIN PACKING:

Input: A list of \( n \) integers \((x_1, x_2, \ldots, x_n)\), given in unary, integers \( B \) and \( k \) such that, \( kB = \sum x_i \).

Task: Find a partition \((P_1, \ldots, P_k)\) of \([n]\) such that, for all \( j \in [k] \), \( \sum_{i \in P_j} x_i = B \).

We reduce to MIN-BKPT-SF as follows: let \( G = (10B)^k \), \( S \) consist of \( m = 2 \) contigs \( C_1 \) and \( C_2 \) with \( C_1 = C_2 = 1 \), let \( T \) contain \( k-1 \) strings 1 and strings \( 0^{x_i} \) for all \( i \in [n] \). Finally, set \( b = 0 \). Consider \( S^* \in S + T \); \( S^* \) yields a partition of \([n]\) into \( k \) subsets \( P_j \), where \( i \in P_j \) if string \( 0^{x_i} \) from \( T \) is inserted between the \((j - 1)\)th and \( j \)th string of \( T \) (or before the first/after the last for \( j = 1 \) and \( j = k \) respectively). Then \( b(S^*, G) = 0 \) if and only if each \( P_j \), \( j \in [k] \), is such that \( \sum_{i \in P_j} x_i = B \). Conversely, any such partition of \([n]\) yields a string in \( S + T \) at distance 0 from \( G \). Hence, the instance \((S, T, G, b = 0)\) of MIN-BKPT-SF is a yes-instance if and only if the original UNARY BIN PACKING instance is a yes-instance.

An FPT Algorithm for the parameter \((|T|, m, b)\). We now present an algorithm for the case that the parameter combines the number \( \tau \) of strings in \( T \), the number of contigs \( m \), and the breakpoint distance \( b \).

Theorem 10. MIN-BKPT-SF is FPT for parameters \(|T|, b \) and \( m \).

Proof. If we consider parameters \(|T| \) and \( m \), then together they allow the exhaustive enumeration of all possible strings in \( S + T \). First, compute the \(|T|\) possible arrangements of strings in \( T \), then split the resulting string into at most \( m \) blocks without breaking substrings corresponding to the strings in \( T \) (this creates at most \( \binom{|T|}{m} \leq 2^{|T|} \) branches), then consider all choices to insert them between the contigs of \( S \) (this creates at most \( 2^m \) branches).

Once a candidate \( S^* \) is known, it remains to compute the breakpoint distance with \( G \) in time \( f(b)n^{O(1)} \) [6]. Overall, this gives an FPT algorithm for parameters \(|T|, b \) and \( m \).

An FPT Algorithm for the parameter \((|T|, d, b)\). The next algorithm is more efficient if the number of duplications \( d \) is small and avoids the dependency on the contig number \( m \).

Theorem 11. MIN-BKPT-SF can be solved in time \( O((4d|T|^2)^{|T|}d^{2b}m^2) \).

Proof. Given an optimal solution \( S^* \), we call \( T \)-factor a maximal factor of \( S^* \) containing strings from \( T \) (a \( T \)-factor is the concatenation of all substrings inserted between two contigs).

A \( T \)-factor is left-joined (resp. right-joined) if there is no breakpoint to its left, i.e., between the last letter of the previous contig and its own first letter (resp., to its right). A \( T \)-factor is stand-alone if it is neither left- nor right-joined. We can assume wlog. that there is a single stand-alone \( T \)-factor, as any two such factors can be inserted in the same gap between two contigs, so that they are merged into one without increasing the distance.

The first step of our algorithm is to guess the \( T \)-factors (using \(|T|^{|T|}\) branches). They will be denoted \( f_1, \ldots, f_h \). For each \( T \)-factor, we guess whether it is left-joined, and whether it is right-joined (using \( 4^{|T|} \) branches). We first deal with the single stand-alone \( T \)-factor, if any: guess the correct gap where it should be inserted (among \( m \leq n \) choices), insert it there and merge it with the surrounding two contigs. Consider now a \( T \)-factor \( f_j \), assume that it is left-joined (otherwise it is necessarily right-joined, then processed symmetrically). Let \( u \) be the first letter of \( f_j \). Guess the position \( i \) such that \( G[i] \) is matched to \( u \) (among \( d \) options). Let \( u' \) be the letter at position \( i - 1 \) in \( G \). Since there is no breakpoint before \( u, f_j \).
must be inserted after a contig ending with $u'$. There are at most $d$ such contigs, so we can enumerate all options. There are at most $d^2$ branches for each $T$-factor, and $d^{2|T|}$ branches overall. The branching above allows to enumerate all candidate strings for a solution, it remains to check whether any of them has breakpoint distance $b$ to $G$. We compute this distance for each candidate, using an FPT algorithm [4] with running time $O(d^2bn)$. The overall running time is $O((d|T|d^2)^{|T|}d^{2b}bn^2)$.

An XP Algorithm for the parameter $b$ when $\lambda = 1$

\textbf{Theorem 12.} \textbf{M}in-\textbf{Bkpt}-\textbf{SF} can be solved in time $O(n^{b+1}(b+1)!)$ when all strings in $\mathcal{T}$ have length 1.

\textbf{Proof.} The algorithm runs as follows: first enumerate all possible positions of the breakpoints in $G$, using $|T|^b$ branches. The optimal string $S^*$ can be guessed by trying all possible rearrangements of the $b+1$ factors separated by breakpoints, using $(b+1)!$ branches.

It remains to check that $S^* \in S + T$, i.e., some filling of $S$ gives $S^*$. This task is NP-hard in the general case (see Theorem 9) however, it is straightforwardly achieved in linear time when all strings in $T$ have length 1: it suffices to check that all contigs in $S$ are factors of $S^*$ in the correct order, and that $T$ contains exactly the multi-set of missing letters.

\section{Conclusion}

For $k$-\textbf{Mer}-\textbf{SF}, the most interesting direction seems to be to extend the problem kernelization to more general cases by allowing either $k > 2$ (that is, considering $k$-mer distance for general $k$), $\lambda > 1$ (that is, allowing the insertion of strings or letters), or considering the case where the number of scaffold contigs is unbounded. For Min-Bkpt-SF it remains open whether the problem is FPT for other parameters than $|T|$, for example $m$, $b$ or $d$. We conjecture that the FPT algorithm for MCSP with parameters $b$ and $d$ [4] can be extended for our problem with this combination of parameters. Hopefully some new techniques might reduce the complexity to achieve fixed-parameter tractability for $b + d$ or $b + \ell$ only.

Finally, from a broader point of view, the problems that we consider here are fundamental on strings. Indeed, they belong to a larger family of problems that can be described as follows: Given a string $G$ and a partial string $S$, complete the partial string $S$ such that it is as close as possible to $G$. Investigating this type of problems more systematically could be a rewarding topic.

Beyond Adjacency Maximization: Scaffold Filling for New String Distances

Then, I contained in any string of at least two adjacencies. The next rule, Rule 3 aims at separating the adjacencies in ▶ Reduction Rule 4.

In this section, we present a kernelization algorithm for the parameter $\ell$ and the special case when $t_2 \geq 2\ell + 1$, $\lambda = 1$ and $k = 2$ and $m$ is a constant.

To obtain a problem kernel, we need to reduce the size of three objects: the genome $G$, the scaffold $S$, and the multiset $\mathcal{T}$ of letters that we may add. We will achieve this in two steps: First, we will reduce the number of copies of letters in $\mathcal{T}$ and of copies of adjacencies and the size of $S$. After this reduction step, we observe that it only remains to reduce the number of different letters in the instance. Consequently, this is what we reduce in the remainder of the algorithm.

Throughout the description of the algorithm, let $x$ denote a letter that does not occur in $S$ and not in $\mathcal{T}$ and let $y$ denote a letter that does not occur in $G$.

The first rule for the kernel removes superfluous copies of letters from $\mathcal{T}$. It is obviously correct, since no solution can add such letters.

► Reduction Rule 2. If $\mathcal{T}$ contains a letter $b$ more than $t_2$ times, remove a copy of $b$ from $\mathcal{T}$.

The next rule, Rule 3 aims at separating the adjacencies in $G$ and keeping only the potential adjacencies in $G$. This will be useful to reduce the size of $G$ but also to reduce the size of $S$, which is done by Rule 4. Recall that the potential common $k$-mers of an instance are the $k$-mers which are contained in $G$ not in $S$. For $k = 2$, we may speak of potential common adjacencies. Also, for a solution $S^*$, we will call the common adjacencies of $S^*$ and $G$ that are not adjacencies of $S$ the realized adjacencies.

► Reduction Rule 3. Let $x$ be a letter that is not contained in any contig of $S$ and not contained in any string of $\mathcal{T}$, and let $p(S,G) := \{P_1, \ldots, P_q\} = a(G) \setminus a(S)$ denote the potential common adjacencies of $G$ and $S$. Replace $G$ by $P_1 \circ x \circ P_2 \circ \cdots \circ P_{q-1} \circ x \circ P_q$.

► Reduction Rule 4. Let $y$ be a letter not contained in $G$. Replace every contig $C_i$ of length at least 2 by $C_i[1] \circ y \circ C_i[[C_i]]$.

► Lemma 13. Let $I = (G,S,\mathcal{T},t_1,t_2)$ be an instance of $k$-MER-SF, and let $I' = (S',\mathcal{T'},t_1',t_2')$ be the instance obtained from $I$ by applying Rules 3 and 4 to $I$. Then, $I$ and $I'$ are equivalent.

Proof. A solution for $I$ realizing at least $\ell$ adjacencies, directly gives a solution for $I'$ realizing at least $\ell$ adjacencies: Every realized adjacency for $I$ is from $p(S,G) = a(G) \setminus a(S)$ and thus contained in $a(G')$. Moreover, it is not contained in $a(S')$ and thus it is a potential common adjacency in $I'$. Now since $\mathcal{T} = \mathcal{T}'$ and since, for any solution of $I$, all realized adjacencies contain either only letters from $\mathcal{T}$ or only the first or the last letter from some contig $C_i$, they can be realized in $I'$ as well by inserting the letters in the same order and between the same contigs as in $I$. The converse direction follows from the same arguments. ▶
Observe that after application of Rule 4, the scaffold has size $O(m)$.

After separating the potential adjacencies in $G$ with the help of Rule 3, we may now speak of removing a copy of a potential adjacency $bc$ from $G$, which means to replace

$$G = P_1 \circ y \circ \cdots \circ P_{i-1} \circ y \circ bc \circ y \circ P_{i+1} \circ \cdots \circ P_q$$

by

$$P_1 \circ y \circ \cdots \circ P_{i-1} \circ y \circ P_{i+1} \circ \cdots \circ P_q$$

for some arbitrary $P_i = bc$.

▶ Reduction Rule 5. If there is a potential adjacency $bc$ that occurs more than $\ell$ times in $G$, then remove a copy of this adjacency from $G$.

Proof of Correctness. Let $I$ denote the original instance and let $I'$ denote the instance obtained by the application of the rule. We need to show only that if $I$ has a solution, then so does $I'$, as the other direction is trivial. Thus, assume that $I$ has a solution realizing at least $\ell$ adjacencies. Choose an arbitrary multiset $P$ of $\ell$ realized adjacencies and observe that there is at least one copy of the adjacency $bc$ in $G$ that is not in $P$. Thus, removing this adjacency from $G$ gives a new genome $G^*$ such that $a(G^*) \setminus a(S) \geq |P| \geq \ell$ since the adjacencies of $P$ are contained in $a(G^*)$. Since the multiset of potential common adjacencies of $G^*$ and of the genome in $I'$ are the same and since the scaffold $S$ and the set $T$ are not changed by the rule, $I'$ has a solution realizing at least $\ell$ common adjacencies.

As the following lemma shows, we have already achieved the goal of the first step, that is, we have reduced the number of copies of all letters in $I$.

▶ Lemma 14. Let $I$ be an instance that is reduced with respect to Rules 1–5, and let $c$ denote the number of different letters occurring in $G$, $S$, and $T$. Then, $|G| \leq 3\ell c^2$ and $|T| \leq c \cdot (2\ell + 1)$.

Proof. First, we bound the size of $G$. If the overall number of letters is $c$, then there are at most $c^2$ different adjacencies in $G$. Moreover, by the construction of $G$, every third adjacency does not contain $x$. Thus, if $|G| > 3\ell c^2$, then there is some adjacency that does not contain the letter $x$ and that occurs more than $\ell$ times. This contradicts the assumption that the instance is reduced with respect to Rule 5.

The bound on the total length of $T$ follows from the fact that $T$ contains at most $c$ many different letters, each of which occurs at most $2\ell + 1$ times since the instance is reduced with respect to Rule 1 and 2.

According to Lemma 14, to obtain a polynomial problem kernel it is sufficient to reduce the number of letters in the instance to $\ell^{O(1)}$. Consequently, this is our aim in the second step of the kernelization algorithm.

First, we remove those letters from $G$ and $T$ which are useless in the sense that they occur in no adjacencies which can become common adjacencies of a solution $S^*$ and $G$.

▶ Definition 15. We call an adjacency $bc$ realizable if $bc$ occurs in $G$, and

- $b \in T$ and $c \in T$, or
- $b = C_i[|C_i|]$ and $c \in T$ for some contig $C_i$, or
- $b = C_i[|C_i|]$ and $c = C_{i+1}[1]$ for some contig $C_i$, or
- $b \in T$ and $c = C_i[1]$ for some contig $C_i$. 

CPM 2017
We now remove those letters that do not occur in realizable adjacencies.

▶ Reduction Rule 6. If \(|T| > t_1\) and \(T\) contains a letter \(b\) that occurs in no realizable adjacency, then remove a copy of \(b\) from \(T\).

If \(G\) contains an adjacency \(bc\) that does not contain \(x\) and that cannot be realized, then remove \(bc\) from \(G\).

The correctness of the rule above follows in a straightforward manner from the fact that we will never insert a letter that is removed by the rule or realize an adjacency that is removed by the rule.

For the final step of the kernelization, we build an auxiliary letter-adjacency graph \(H = (V, E)\) as follows. For each letter in \(T, G,\) and \(S\), add one vertex to \(H\). Make two vertices \(b\) and \(c\) adjacent in this graph if the adjacency \(bc\) or the adjacency \(cb\) is realizable. Observe that after application of Rule 6, every vertex in \(H\) except \(x, y\), and possibly the \(2m - 2\) vertices corresponding to letters of contigs, has at least one neighbor. Thus, our aim in the following is to reduce the number of vertices in \(H\) that have at least one neighbor.

▶ Reduction Rule 7. Let \(M\) be a maximum matching in \(G\). If \(|M| \geq \ell + 1\), then answer “yes”.

Proof of Correctness. We show how to construct a solution for the \(k\)-MER-SF instance. Let \(\{\{b_1, c_1\}, \{b_2, c_2\}, \ldots, \{b_t, c_t\}\}\) be a set of \(\ell + 1\) edges contained in \(M\) and assume without loss of generality that \(b_i c_i\) is a realizable adjacency for each \(i\).

First, assume that for all \(i \in [\ell + 1]\) either \(b_i \in T\) or \(c_i \in T\). For each \(i\), do the following. If \(b_i \in T\) and \(c_i \in T\), add \(b_i c_i\) between \(C_1\) and \(C_2\). If \(b_i \in T\) and \(c_i = C_j[1]\) for some \(C_j\), then add \(b_i\) directly in front of \(C_j\). If \(b_i = C_j[1]\) and \(c_i \in T\), then add \(c_i\) directly after \(C_j\). The set of inserted letters realizes at least \(\ell + 1\) adjacencies, since the \(\ell + 1\) pairs \(\{b_i, c_i\}\) are disjoint and since for each we realize one adjacency. To obtain a feasible solution, insert \(t_1 - (\ell + 1)\) further letters at an arbitrarily chosen position. This breaks at most one adjacency thus giving a solution that realizes at least \(\ell\) adjacencies.

If for some \(i\), we have \(b_i = C_j[1]\) and \(c_i = C_j[1]\), then choose an arbitrary such \(i\) and add all adjacencies \(b_i c_q\) with \(b_q \in T\) and \(c_q \in T\) between \(C_j\) and \(C_{j+1}\). Add \(t_1 - (\ell + 1)\) further letters right before \(C_{j+1}\). Insert all other letters as described above. The number of realized adjacencies is at least \(\ell\). All adjacencies of \(M\) except the adjacency \(b_i c_q\) are realized: if at least one letter in the adjacency is from \(T\), then they are realized because this letter is inserted in the right position. If neither \(b_i\) nor \(c_q\) are from \(T\), then the adjacency is realized because no letters are inserted between the consecutive contigs that contain \(b_i\) and \(c_q\).

Now let \(V(M)\) denote the endpoints of the matching. We show that if \(|V \setminus V(M)| > (2\ell + m) \cdot |V(M)|\), then we can safely remove some adjacency from \(G\).

To apply the next rule, we build two bipartite graphs \(H^1\) and \(H^2\). In both graphs, the vertex parts are \(B := V(M)\) and \(C := (V \setminus V(M))\). In \(H^1\), we add an edge between \(b \in B\) and \(c \in C\) when \(bc\) is a realizable adjacency. In \(H^2\), we add an edge between \(b \in B\) and \(c \in C\) when \(cb\) is a realizable adjacency.

▶ Reduction Rule 8.
- If there is a vertex \(b \in B\) of degree at least \(2\ell + m + 1\) in \(H^1\), then remove the adjacency \(bc\) from \(G\), where \(c\) is an arbitrary neighbor of \(b\).
- If there is a vertex \(b \in B\) of degree at least \(2\ell + m + 1\) in \(H^2\), then remove the adjacency \(cb\) from \(G\), where \(c\) is an arbitrary neighbor of \(b\).
Proof of Correctness. We show the correctness for the first part of the rule, the second part is symmetric. Consider an instance before application of the rule and assume it has a solution realizing at least \( \ell \) adjacencies. If none of these adjacencies is \( bc \), the adjacency removed from \( G \) by the rule, then this solution directly implies a solution for the reduced instance. Otherwise, fix an arbitrary minimal set \( P \) of positions containing a letter of the \( \ell \) many realized adjacencies. Observe that \( |P| \leq 2\ell \) and there are at most \( \ell \) pairs of consecutive contigs that have nonempty intersection with these positions. Now, consider the adjacency \( bc \) that is contained in the solution but not contained in \( G \). There are at least \( m + 1 \) letters \( d \) that are adjacent to \( b \) in \( H^1 \) such that not all copies of \( d \) are contained in \( P \). Of these, at most \( m \) are letters from contigs. Thus, there is a \( d \) such that \( d \in T \) and not all copies of \( d \) are contained in \( P \). Therefore, inserting \( d \) behind \( b \) destroys the adjacency \( bc \), but instead creates the adjacency \( bd \). This adjacency is also contained in \( G \) and not realized by any position of \( P \). This restores the number of realized adjacencies to \( \ell \).

\[ \triangleright \]

**Theorem 7.** For \( k = 2 \), \( \lambda = 1 \) and \( t_2 \geq 2\ell + 1 \), \( k \)-MER-SF admits a problem kernel of size \( O(\ell^3 \cdot (\ell + m)^2) \) that can be computed in polynomial time.

**Proof.** Consider an instance that is reduced with respect to all presented reduction rules. By Lemma 14, our claim follows if we show that the number of letters in \( I \) is \( O(\ell \cdot (\ell + m)) \). This can be seen by considering the graph \( H \): the graph \( H \) has \( O(m) \) vertices that have no neighbors. The number of further vertices is \( O(\ell \cdot (\ell + m)) \): After applying Rule 7, the size of the matching \( M \) is \( O(\ell) \). Any vertex in \( H \) that is incident with at least one edge and not an endpoint of \( M \) is adjacent to a vertex of \( M \) either in \( H^1 \) or in \( H^2 \). After applying Rule 8, the number of these vertices is at most \( |V(M)| \cdot 2 \cdot (2\ell + m + 1) = O(\ell \cdot (\ell + m)) \). This gives the bound on the number of vertices in \( G \) and thus on the instance size.

The running time follows from the fact that all reduction rules can be clearly performed in polynomial time.

Abstract

In phylogenetics, the consensus problem consists in summarizing a set of phylogenetic trees that all classify the same set of species into a single tree. Several definitions of consensus exist in the literature; in this paper we focus on the Weighted Quartet Consensus problem, a problem with unknown complexity status so far. Here we prove that the Weighted Quartet Consensus problem is NP-hard and we give a 1/2-factor approximation for this problem. During the process, we propose a derandomization procedure of a previously known randomized 1/3-factor approximation. We also investigate the fixed-parameter tractability of this problem.

1 Introduction

Phylogenetics is the branch of biology that studies evolutionary relationships among different species. These relationships are represented via phylogenetic trees – acyclic connected graphs with leaves labeled by species – which are reconstructed from molecular and morphological data [12]. One fundamental problem in phylogenetics is to summarize the information contained in a set of unrooted trees $T$ classifying the same set of species into a single tree $T$. The set $T$ can consist of optimal trees for a single data set, of trees issued from a bootstrap analysis of a unique data set, or even of trees issued from the analysis of different data sets. Several consensus methods have been proposed in the past, the probably most known are the strict consensus [23, 18] and the majority-rule consensus [17, 3]. For a survey, see [7].

In this paper we focus on the Weighted Quartet Consensus (WQC) problem [19], also called the Median Tree with Respect to Quartet Distance problem [2] and Quartet Consensus problem in [16]. Roughly speaking, this problem consists in finding a consensus tree maximizing the weights of the 4-leaf trees – quartets – it displays, where the weight of a quartet is defined as its frequency in the set of input trees (for a more formal definition, see next section).

More general versions of this problem, where the input trees are allowed to have missing species or where the weight of a quartet is not defined w.r.t. a set of trees, are known to be
On the Weighted Quartet Consensus Problem

NP-hard [24] (and in fact, even Max-SNP-Hard), but the complexity of the WQC problem has remained open so far. This problem has been conjectured to be NP-hard [2, 19], and heuristics have recently been implemented and widely used, for instance ASTRAL [20], which is a practical implementation of Bryant and Steel’s work from [8] (in fact, we show that the ASTRAL algorithm is a 2-approximation for the minimization version of WQC). So far, the best known approximation algorithm for the WQC problem consists in choosing a random tree as a solution [16]. This tree is expected to contain a third of the quartets from the input trees, and so it is a randomized factor 1/3 approximation. In [2], the minimization version of the problem is studied, where the objective is to find a median tree \( T \) minimizing the sum of quartet distances between \( T \) and the input trees (the quartet distance between two trees \( T_1 \) and \( T_2 \) is defined as the number of quartets in \( T_1 \) that are not in \( T_2 \)). A 2-approximation algorithm is given, based on the fact that the quartet distance is a metric [9, 2].

A related problem that has received more attention is the Complete Maximum Quartet Compatibility problem (CMQC) (see [5, 4, 16, 14, 25, 26, 10, 21, 22]). In the CMQC problem, we are given, for each set \( S \) of four species, exactly one quartet on \( S \), and the objective is to find a tree containing a maximum number of quartets from the input. This can be seen as a version of WQC in which each set of four species has one quartet of weight 1, and the others have weight 0. The CMQC and WQC are however fundamentally different. Although one could apply an algorithm for CMQC to WQC (by keeping only the most frequent quartet on each set of four taxa), maximizing the most-frequent quartets may enforce the presence of many low-frequency quartets. A better solution may prefer more of the middle-frequency quartets, and we give an example of this phenomenon. It was shown in [16] that the CMQC problem admits a polynomial time approximation scheme (PTAS), but it can only be extended to WQC instances on a constant number of trees. Also, CMQC was shown in [14, 10] to be fixed-parameter tractable w.r.t. the parameter “number of quartets to reject from the input”.

The main result of this paper is to establish the NP-hardness of the WQC problem. In Section 2, we introduce preliminary notions, and in Section 3 we propose a reduction from the NP-hard Cyclic Ordering problem to WQC. It can be shown that this hardness result transfers to the rooted setting, in which case we want to optimize triplets (3-leaf rooted trees) rather than quartets. In Section 4, we discuss how being in a consensus setting, i.e. having weights based on a set of input trees on the same leaf set rather than arbitrary weights, does not necessarily make the problem easier, as one could expect: We list some structural properties that, surprisingly, are not satisfied by optimal solutions of a WQC instance. Nevertheless, in Section 5 we devise a factor 1/2 approximation algorithm for WQC running in time \( O(k^2n^2 + kn^4 + n^5) \), where \( k \) is the number of trees and \( n \) the number of species (the best known randomized algorithm in the non-consensus setting is a factor 1/3 one). As a matter of fact, our algorithm includes a derandomization of this procedure, which had never been done before. Finally in Section 6, we show that the known FPT algorithms for the CMQC problem can be extended to the consensus setting. This yields an FPT algorithm that is efficient on instances in which there is not too much ambiguity, i.e. when few competing quartets on the same 4 species appear with the same frequency. We then conclude with some remarks and open problems related to the quartet consensus problem.

2 Preliminaries

An unrooted phylogenetic tree \( T \) consists of vertices connected by edges, in which every pair of nodes is connected by exactly one path and no vertex is of degree two. The leaves of a tree
A phylogenetic tree is defined in the same way, except that it has exactly one node of degree two called the root, denoted by \( r(T) \). Note that sometimes in the literature, rooted trees are seen as directed and such that all arcs are oriented away from the root. Unless stated otherwise, all trees in this paper are unrooted.

Given an unrooted phylogenetic tree \( T \) and a subset \( Y \subseteq \mathcal{L}(T) \), we denote by \( T|Y \) the tree obtained from the minimal subgraph of \( T \) connecting \( Y \) when contracting degree-2 vertices.

A quadset is a set of four labels. For a quadset \( \{a, b, c, d\} \), there are three non-isomorphic\(^1\) unrooted binary trees, called quartets, which are denoted respectively by \( ab|cd \), \( ac|bd \), and \( ad|bc \), depending on how the central edge splits the four labels. We say that an unrooted tree \( T \) displays the quartet \( ab|cd \) if \( T|\{a, b, c, d\} \) is \( ab|cd \). We denote the set of quartets that an unrooted tree \( T \) displays by \( Q(T) \). Note that if \( T \) is binary, then \( |Q(T)| = \binom{|\mathcal{L}(T)|}{4} \). A set of quartets \( Q \) on a set \( L \) is said to be complete if for each quadset \( \{a, b, c, d\} \subseteq L \), there is in \( Q \) exactly one quartet among \( ab|cd \), \( ac|bd \), and \( bc|ad \).

We are now ready to state our optimization problem. The **Weighted Quartet Consensus (WQC)** problem asks for a tree that has as many quartets as possible in common with a given set of trees on the same set of labels \( \mathcal{X} \):

**Weighted Quartet Consensus (WQC) problem**

**Input:** a set of unrooted trees \( T = \{T_1, \ldots, T_k\} \) such that \( \mathcal{L}(T_1) = \ldots = \mathcal{L}(T_k) = \mathcal{X} \).

**Output:** a binary unrooted tree \( M \) with \( \mathcal{L}(M) = \mathcal{X} \) that maximizes \( \sum_{T \in T} |Q(M) \cap Q(T)| \).

The problem is weighted as each quartet on \( \mathcal{X} \) is weighted by frequency in \( T \), see below.

In this paper we will focus on the particular case where the input trees are all binary. In fact, proving the problem NP-hard for this restricted case implies NP-hardness of the general problem. Note however that relaxing the requirement of the output \( M \) to be binary leads to a different problem, as one needs to define how unresolved quartets in \( M \) are weighted.

In the remainder of the article, we will sometimes consider multi-sets of quartets, that are sets in which the same quartet can appear multiple times. Denote by \( f_Q(q) \) the number of times that a quartet \( q \) appears in a multi-set \( Q \) (we may write \( f(q) \) if \( Q \) is unambiguous).

We say that a tree \( T \) contains \( k \) quartets of \( Q \) if there are distinct quartets \( q_1, \ldots, q_p \in Q(T) \) such that \( \sum_{i=1}^p f(q_i) = k \). The Weighted Quartet Consensus problem can be rephrased as follows: given trees \( T_1, \ldots, T_k \), finding a tree \( M \) that contains a maximum number of quartets from \( Q(T_1) \uplus Q(T_2) \uplus \ldots \uplus Q(T_k) \), where \( \uplus \) denotes multiset union. We will implicitly work with the decision version of WQC, i.e. for a given integer \( q \), is there a consensus tree \( M \) containing at least \( q \) quartets from \( Q(T_1) \uplus Q(T_2) \uplus \ldots \uplus Q(T_k) \)?

Given a quadset \( \{a, b, c, d\} \), we say that \( ab|cd \) is dominant (w.r.t. \( f \)) if \( f(ab|cd) \geq f(ac|bd) \) and \( f(ab|cd) \geq f(ad|bc) \). We say that \( ab|cd \) is strictly dominant if both inequalities are strict.

---

\(^1\) Isomorphism preserving labels.
3 NP-hardness of the Weighted Quartet Consensus problem

In this section, we present a reduction from the CYCLIC ORDERING problem. This problem has been used in phylogenetics before in [15] in the context of inferring rooted binary trees from rooted triplets that are not required to originate from a set of trees on the same leaf set.

But beforehand, we need some additional notation. A caterpillar is an unrooted binary tree obtained by taking a path \( P = p_1p_2\ldots p_r \), then adding a leaf \( \ell_1 \) adjacent to \( p_1 \) for each \( 1 \leq i \leq r \), then adding another leaf \( \ell'_1 \) adjacent to \( p_1 \) and a leaf \( \ell''_1 \) adjacent to \( p_r \). The two leaves \( \ell'_1 \) and \( \ell''_1 \) inserted last are called the ends of the caterpillar. An augmented caterpillar \( T \) is a binary tree obtained by taking a caterpillar, then replacing each leaf by a binary rooted tree (replacing a leaf \( \ell \) by a tree \( T' \) means replacing \( \ell \) by \( r(T') \)). If \( T_1, T_2 \) are the two trees replacing the ends of the caterpillar, then \( T \) is called a \((T_1, T_2)\)-augmented caterpillar.

Note that every binary tree is a \((T_1, T_2)\)-augmented caterpillar for some \( T_1, T_2 \). Let \( T \) be a caterpillar with leaves \( (\ell_1, \ell_2, \ldots, \ell_k) \) taken in the order in which we encounter them on the path between the two ends \( \ell_1 \) and \( \ell_k \) (more precisely, traverse the \( \ell_1 - \ell_k \) path, and each time an internal node is encountered, append its adjacent leaves to the sequence), and let \( T_1, \ldots, T_k \) be rooted binary trees. We denote by \((T_1|T_2|\ldots|T_k)\) the \((T_1, T_k)\)-augmented caterpillar obtained by replacing \( \ell_i \) by \( r(T_i) \), \( 1 \leq i \leq k \). This notation gives rise to a natural ordering of its subtrees, and we say that \( T_i < T_j \) if \( i < j \) (i.e. \( T_i \) appears before \( T_j \) in the given ordering of the caterpillar subtrees). Note that by reversing such an ordering, we obtain the same unrooted tree. However, in the proofs the given ordering will be important. Also, since \( T_1, T_2, \) and \( T_{k-1}, T_k \) are interchangeable, we will simply say that these two pairs are incomparable. If each \( T_i \) consists of a single leaf \( \ell_i \) for \( 2 \leq i \leq k-1 \), then we may write \((T_1|T_2|\ldots|T_{k-1}|T_k)\), and \( \ell_i < \ell_j \) in \( T \) to indicate that \( \ell_i \) appears before \( \ell_j \) in the ordering.

We are now ready to describe the CYCLIC ORDERING problem. Let \( L = (s_1, \ldots, s_n) \) be a linear ordering of a set \( S \) of at least \( 3 \) elements, and let \((a, b, c)\) be an ordered triple, with \( a, b, c \in S \). We say that \( L \) satisfies \((a, b, c)\) if one of the following holds in \( L \): 
\[ a < b < c, \quad b < c < a, \quad \text{or} \quad c < a < b. \]
If \( C \) is a set of ordered triples we say that \( L \) satisfies \( C \) if it satisfies every element of \( C \). Intuitively speaking, \( L \) satisfies \((a, b, c)\) when, by turning \( L \) into a directed cyclic order by attaching \( s_n \) to \( s_1 \), one can go from \( a \) to \( b \), then to \( c \) and then to \( a \). This leads to the following problem definition:

**Cyclic Ordering problem**

**Input:** A set \( S \) of \( n \) elements and a set \( C \) of \( m \) ordered triples \((a, b, c)\) of distinct members of \( S \).

**Question:** Does there exist a linear ordering \( L = (s_1, \ldots, s_n) \) of \( S \) that satisfies \( C \)?

The CYCLIC ORDERING problem is NP-hard [13]. In the rest of this section, we let \( S \) and \( C \) be the input set and triples, respectively, of a CYCLIC ORDERING problem instance. We denote \( n = |S| \) and \( m = |C| \). We shall use the following simple yet useful characterization.

**Lemma 1.** A linear ordering \( L \) of \( S \) satisfies \( C \) if and only if for each \((a, b, c)\in C\), exactly two of the following relations hold in \( L \): \( a < b, b < c, c < a \).

**Proof.** \((\Rightarrow)\): let \( L \) be a linear ordering satisfying \( C \), and let \((a, b, c)\in C\). Thus in \( L \), one of \( a < b < c, b < c < a, \) or \( c < a < b \) holds. It is straightforward to verify that in each case, exactly two of \( a < b, b < c, c < a \) hold.

\((\Leftarrow)\): suppose that \( L \) does not satisfy \( C \). Then there is some \((a, b, c)\in C\) such that one of \( a < c < b, b < a < c, \) or \( c < b < a \) does not hold. Again, one can easily verify that each of these cases satisfies only one of \( a < b, b < c \) and \( c < a \). \(\blacksquare\)
Now, from $S$ and $C$ we construct a set of unrooted binary trees $T$ on the same set of labels (we will omit the straightforward verification that this construction can be carried out in polynomial time). First let $W$ and $Z$ be two rooted binary trees each on $(nm)^{100}$ leaves (the topology is arbitrary, and the 100 exponent could be optimized). Our trees are defined on the leaf set $\mathcal{X} = S \cup \mathcal{L}(W) \cup \mathcal{L}(Z)$ (note that $S, \mathcal{L}(W), \mathcal{L}(Z)$ are disjoint). Let $C \in \mathcal{C}$ with $C = (a, b, c)$. We construct 6 trees from $C$, that is, 3 pairs of trees:

- The “$a < b$” trees: let $(s_1, \ldots, s_{n-2})$ be an arbitrary ordering of $S \setminus \{a, b\}$. Then we build the trees $T_C(ab) = (W[a][b][s_1][s_2][\ldots][s_{n-2}][Z]$ and $\overline{T_C(ab)} = (W[s_{n-2}][s_{n-3}][\ldots][s_1][a][b][Z]).$
- The “$b < c$” trees: let $(\hat{s}_1, \ldots, \hat{s}_{n-2})$ be an arbitrary ordering of $S \setminus \{b, c\}$. Then we build the trees $T_C(bc) = (W[b][c][s_1][s_2][\ldots][s_{n-2}][Z]$ and $\overline{T_C(bc)} = (W[\hat{s}_{n-2}][\hat{s}_{n-3}][\ldots][\hat{s}_1][b][c][Z]).$
- The “$c < a$” trees: let $(\tilde{s}_1, \ldots, \tilde{s}_{n-2})$ be an arbitrary ordering of $S \setminus \{c, a\}$. Then we build the trees $T_C(ca) = (W[c][a][\tilde{s}_1][\tilde{s}_2][\ldots][\tilde{s}_{n-2}][Z]$ and $\overline{T_C(ca)} = (W[\tilde{s}_{n-2}][\tilde{s}_{n-3}][\ldots][\tilde{s}_1][a][c][Z]).$

Denote by $\mathcal{T}(C)$ the set of 6 constructed trees for $C \in \mathcal{C}$. In this section, the input for our Weighted Quartet Consensus instance constructed from $S$ and $C$ is $T = \bigcup_{C \in \mathcal{C}} \mathcal{T}(C)$. Note that $|T| = 6m$.

Observe that each tree of $\mathcal{T}(C)$ is a $(W, Z)$-augmented caterpillar. Moreover, note that the majority of ordered pairs are “balanced” in the pairs of constructed trees: Let $a, b \in S$ and $x, y \in S \setminus \{a, b\}$, and let $\{T_C(ab), \overline{T_C(ab)}\}$ be an “$a < b$” tree-pair. Then we have $x < y$ in $T_C(ab)$ if and only if $y < x$ in $\overline{T_C(ab)}$. Similarly for any $x \in S \setminus \{a, b\}$, $a < x, b < x$ in $T_C(ab)$ but $x < a, x < b$ in $\overline{T_C(ab)}$. Only $a < b$ holds in both trees.

Let $T \in \mathcal{T}$, and let $B(T)$ denote the set of quartets of $T$ that have at least two members of $\mathcal{L}(W)$, or at least two members of $\mathcal{L}(Z)$. Thus $B(T)$ consists in all the quartets of the form $w_1w_2[xy]$ and $z_1z_2[xy]$ of $T$, where $w_1, w_2 \in \mathcal{L}(W), z_1, z_2 \in \mathcal{L}(Z)$ and $x, y \in \mathcal{X}$ (note that no quartet of $B(T)$ has the form $w_1x[w_2y$ for $x, y \notin \mathcal{L}(W)$, nor the form $z_1x[z_2y$ for $x, y \notin \mathcal{L}(Z)$). Note that for any tree $T \in \mathcal{T}$, $B(T) = B(T^\prime)$. Let $K := 6m|B(T)|$ be the total number of such quartets in $T$, i.e. $K$ is the size of $\bigcup_{T \in \mathcal{T}} B(T)$. We observe the following:

**Remark.** Any $(W, Z)$-augmented caterpillar on $\mathcal{X}$ contains the $K$ quartets $\bigcup_{T \in \mathcal{T}} B(T)$.

Now, denote $\hat{O} := 3m|W||Z|((n-2)^2 + 2(n - 2))$. Let $T \in \mathcal{T}$ and suppose that $T$ is an “$a < b$” tree, for some $a, b \in S$ and $x, y \in S \setminus \{a, b\}$. Then $T$ contains exactly $\hat{O}$ quartets from $\bigcup_{T \in \mathcal{T}} out(T)$. Moreover, if $M$ is a $(W, Z)$-augmented caterpillar $(W[s_1][\ldots][s_n][Z]$ where $S = \{s_1, \ldots, s_n\}$, then $M$ contains exactly $\hat{O}$ quartets from $\bigcup_{T \in \mathcal{T}} out(T)$.

**Lemma 2.** Any weighted quartet consensus tree $M$ for $T$ contains at most $\hat{O}$ quartets from $\bigcup_{T \in \mathcal{T}} out(T)$. Moreover, if $M$ is a $(W, Z)$-augmented caterpillar $(W[s_1][\ldots][s_n][Z]$ where $S = \{s_1, \ldots, s_n\}$, then $M$ contains exactly $\hat{O}$ quartets from $\bigcup_{T \in \mathcal{T}} out(T)$.

**Proof.** Let $w \in \mathcal{L}(W)$ and $z \in \mathcal{L}(Z)$. Let $\{T_C(ab), \overline{T_C(ab)}\}$ be an “$a < b$” tree-pair of $T$, for some $a, b \in S$, and let $x, y \in S$ such that $\{x, y\} \neq \{a, b\}$. Because $x < y$ in $T_C(ab)$ if and only if $y < x$ in $\overline{T_C(ab)}$, we get that the out-quartet $wx|yz$ is in $T_C(ab)$ if and only if $wz|xy$ is in $\overline{T_C(ab)}$. Since $M$ can only contain one of the two quartets, it follows that $M$ can contain at most $\hat{O}$ quartets from $out(T_C(ab)) \cup out(\overline{T_C(ab)})$. Thus $M$ contains at most $\hat{O}$ quartets from $\bigcup_{T \in \mathcal{T}} out(T)$, which is $3m|W||Z|((n-2)^2 + 2(n - 2)) = \hat{O}$. As for the second assertion, if $M = (W[s_1][\ldots][s_n][Z]$ then $M$ contains one of $wx|yz$ or $wz|xy$ for each $x, y \in S$. Thus if $M$ does not contain the out-quartet $wx|yz$ from $T_C(ab)$, then it...
contains the out-quartet \( wy|xz \) from \( \overline{T}_C(ab) \). We deduce that \( M \) contains at least half the quartets from \( out(T_C(ab)) \) \( \geq out(\overline{T}_C(ab)) \), and thus half the quartets from \( \bigcup_{T \in \mathcal{T}} out(T) \). ▶

What follows is a key Lemma. The proof is not so straightforward and can be found in Appendix B.1.

Lemma 3. Any optimal consensus tree for \( T \) is a \((W, Z)\)-augmented caterpillar.

We finally arrive at our main result.

Theorem 4. The Weighted Quartet Consensus problem is NP-hard.

Proof. We show that there exists a linear ordering of \( S \) satisfying \( C \) if and only if there exists a weighted quartet consensus tree \( M \) for \( T \) that contains at least \( K + \hat{O} + 4m|W||Z| \) quartets from \( \bigcup_{T \in \mathcal{T}} Q(T) \). For the rest of the proof, we let \( w \in \mathcal{L}(W) \) and \( z \in \mathcal{L}(Z) \) be arbitrary leaves of \( W \) and \( Z \), respectively.

\((\Rightarrow)\): let \( L = (s_1, s_2, \ldots, s_n) \) be a linear ordering of \( S \) satisfying \( C \). Then we claim that the weighted quartet consensus tree \( M = (W|s_1s_2|\ldots|s_n|Z) \) contains the desired number of quartets. Since \( M \) is a \((W, Z)\)-augmented caterpillar, \( M \) contains \( K \) quartets of \( T \) that have two or more elements from \( \mathcal{L}(W) \), or two or more elements from \( \mathcal{L}(Z) \), see remark on page 5. Moreover by Lemma 2, \( M \) contains \( \hat{O} \) quartets from \( \bigcup_{T \in \mathcal{T}} out(T) \). As for the in-quartets, let \( (a, b, c) \in C \) and let \( T((a, b, c)) \) be the set of 6 trees corresponding to \( (a, b, c) \). By Lemma 1, \( L \) satisfies two of the relations \( a < b, b < c, c < a \). This implies that \( M \) has exactly two of the following quartets: \( wab|bc \), \( wb|cz \), \( wc|az \). Since, for every \( w \in \mathcal{L}(W) \) and \( z \in \mathcal{L}(Z) \), each of these three quartets appears as an in-quartet in exactly two of \( T((a, b, c)) \) (e.g. \( wab|bc \) is an in-quartet of \( T_{(a, b, c)}(ab) \) and \( \overline{T}_{(a, b, c)}(ab) \)). If \( T \) contains 4\(|W||Z| \) quartets from \( \bigcup_{T \in \mathcal{T}} in(T) \). As this holds for every \( (a, b, c) \in C \), \( M \) contains 4\(|W||Z| \) quartets from \( \bigcup_{T \in \mathcal{T}} in(T) \). Summing up, we get that \( M \) has at least \( K + \hat{O} + 4m|W||Z| \) quartets from \( T \).

\((\Leftarrow)\): suppose that no linear ordering of \( S \) satisfies \( C \). Let \( M \) be an optimal consensus tree for \( T \). By Lemma 3, we may assume that \( M \) is a \((W, Z)\)-augmented caterpillar. We bound the number of quartets of \( T \) that can be contained in \( M \).

First, by Lemma 3, \( M \) contains \( K \) quartets of \( T \) that have at least two elements of \( \mathcal{L}(W) \) or at least two elements of \( \mathcal{L}(Z) \). As for the quartets with one or zero elements from \( \mathcal{L}(W) \) \( \cup \mathcal{L}(Z) \), in any tree \( T \in \mathcal{T} \) there are at most \( (|W| + |Z|)n^3 \) quartets of the form \( wab|bc \) or \( z|bc \) with \( a, b, c \in S \), and at most \( n^4 \) quartets of the form \( ab|cd \) with \( a, b, c, d \in S \). Thus \( M \) contains at most \( 6m(|W| + |Z|)n^3 + n^4 \) \( < (|W| + |Z|)(m+1)^5 \) quartets of \( T \) that are of the form \( wab|bc \), \( z|bc \) or \( ab|cd \) with \( a, b, c \in S \) (the inequality holds because \( n \geq 3 \) and \( |W| = |Z| = (nm)^{100} \)). Also, by Lemma 2, \( M \) contains at most \( \hat{O} \) quartets from \( \bigcup_{T \in \mathcal{T}} out(T) \). It remains to count the in-quartets.

Let \( (a, b, c) \in C \). The following in-quartets appear, each twice, in \( T((a, b, c)) \): \( wab|bc \), \( wb|cz \), \( wc|az \). It is easy to check that these three quartets are incompatible, i.e. no tree can contain all three of them, and hence \( M \) can have at most two of them. We deduce that \( M \) must be at least two trees, \( T, \overline{T} \) of \( T((a, b, c)) \) such that \( M \) contains no quartet from \( in(T) \) \( \cup in(\overline{T}) \). Therefore \( M \) contains at most \( 4|W||Z| \) quartets from \( \bigcup_{T \in \mathcal{T}} in(T) \), and thus at most \( 4m|W||Z| \) quartets from \( \bigcup_{T \in \mathcal{T}} in(T) \) assuming that the \( 4|W||Z| \) bound is attained for every \( (a, b, c) \in C \). We will however show that there must be some \((a, b, c) \in \mathcal{C} \) such that \( M \) contains only \( 2|W||Z| \) of the quartets in \( \bigcup_{T \in \mathcal{T}} in(T) \).

Now, since \( M \) is a \((W, Z)\)-augmented caterpillar, we write \( M = (W|T_1|T_2|\ldots|T_k|Z) \). For some \( a \in S \), let \( T(a) \) be the tree of \( \{T_1, \ldots, T_k\} \) that contains \( a \) as a leaf. Then a quartet \( wab|bc \) is in \( Q(M) \) if and only if \( T(a) < T(b) \). Let \( L \) be a linear ordering of \( S \) such
that \( T(a) < T(b) \Rightarrow a < b \) in \( L \). Since no linear ordering of \( S \) can satisfy \( C \), by Lemma 1 there must be some \( (a, b, c) \in C \) such that only one of \( a < b, b < c, c < a \) holds in \( L \). This also means that at most one of \( T(a) < T(b), T(b) < T(c), T(c) < T(a) \) holds (because \( \neg(a < b) \Rightarrow \neg(T(a) < T(b)) \)). Thus \( M \) has at most one of the \( \abbc, \abcc, \abc \) quartets.

It follows that there are at least \( 2|W||Z| \) quartets from \( \bigcup_{T \in \mathcal{T}} \text{in}(T) \) that \( M \) does not contain. Therefore \( M \) contains at most \( 4m|W||Z| - 2|W||Z| \) quartets of \( \bigcup_{T \in \mathcal{T}} \text{in}(T) \).

In total, the number of quartets that \( M \) contains from the input is bounded by \( K + \hat{O} + (|W| + |Z|)^{m^5} + (4m - 2)|W||Z| < K + \hat{O} + 4m|W||Z| \), by our choice of \(|W|\) and \(|Z|\).

The implications of these results for the Weighted Triplet Consensus (WTC) problem are presented in Appendix A. The same techniques can be used to show that WTC is NP-hard.

## 4 The (non)-structure of WQC

In the rest of this paper, we aim at designing algorithms building on the fact that the weight of each quartet is not arbitrary, and is rather based on a set of input trees on the same leaf set. When designing optimized algorithms for a problem, understanding the relationship between the input and the optimal solution(s) can be of great help. In phylogenetics, several problems are harder in the supertree setting, i.e. when the input trees do not all contain the same species, than in the consensus setting as in the WQC problem. An example is the problem of finding an unrooted phylogenetic tree containing as minors a set of unrooted phylogenetic trees – the compatibility problem – which is NP-hard in the supertree setting [24] and polynomially solvable in the consensus setting [1]. Despite the NP-hardness of WQC, there may exist some properties inherent to the consensus setting that are useful for devising efficient FPT algorithm, or for establishing lower bounds on the value of an optimal solution in order to develop approximation algorithms.

In attempt to establish useful properties of the weights of quartets in the consensus setting, we initially conjectured that the following relationships between the input trees and the solution(s) hold. Despite being seemingly reasonable, we prove all these conjectures false.

1. let \( D \) be the set of strictly dominant quartets of the input multiset \( \mathcal{Q} \), i.e. the quartets \( \abbc \) such that \( f(\abbc) > f(\acb) \) and \( f(\abbc) > f(\adc) \). Then there is a constant \( \alpha > 0 \) such that there exists an optimal solution containing at least \( \alpha|D| \) quartets of \( D \);

2. if a quartet \( \abbc \) has a higher weight than the sum of the other quartets on the same quadset, i.e. \( f(\abbc) > f(\acb) + f(\adc) \), then some optimal solution contains \( \abbc \);

3. more generally, there exists \( \beta > 0 \) such that if a quartet \( \abbc \) is in a fraction \( \beta \) of the input trees, then \( \abbc \) must be in some optimal solution. In particular, if \( \abbc \) is in every input tree, then there is some optimal solution that contains \( \abbc \);

4. if a quartet \( \abbc \) is in no input tree, then no optimal solution contains \( \abbc \);

5. call \( \abbc \) a strictly least-frequent quartet if \( f(\abbc) < f(\acb) \) and \( f(\abbc) < f(\adc) \). Suppose that there exists a tree \( T^* \) on leaf set \( X \) that contains no strictly least-frequent quartet, and choose such a \( T^* \) that contains a maximum number of quartets from the input. Then \( T^* \) is an optimal solution for WQC.

Unfortunately, we answered negatively to all conjectures, see Appendix B.2.

## 5 Approximability of WQC

In this section, we show that WQC admits a factor 1/2 approximation algorithm that runs in polynomial time. Hereafter, the input set of trees is \( \mathcal{T} = \{T_1, \ldots, T_k\} \) and we denote
We say that a minimization (resp. maximization) problem $P$ can be approximated within a factor $\alpha > 1$ (resp. $\beta < 1$) if there is an algorithm that, for every instance $I$ of $P$, runs in polynomial time and outputs a solution of value $APP(I)$ such that $APP(I) \leq \alpha OPT(I)$ (resp. $APP(I) \geq \beta OPT(I)$), where $OPT(I)$ is the optimal value of $I$.

As mentioned before, the Complete Maximum Quartet Compatibility (CMQC) problem admits a PTAS, though it can only be applied to the WQC problem when the number of input trees is constant. There does not seem to exist an easy extension of the PTAS algorithm for the case of an unbounded number of trees, which makes WQC seem “harder” than CMQC. Nevertheless, we give a simple factor $1/2$ approximation algorithm, which is better than the (randomized) factor $1/3$ approximation, the best known so far, for the general Maximum Quartet Consistency problem in which the given quartet set is not necessarily complete. We borrow ideas from [9] to show that this can be achieved by taking the best tree from the input. Intuitively, the input tree that is the closest to the others cannot be too far from the best solution, which is a median tree in the metric space. See [2] for details.

It is not hard to show that $d_Q$ is a metric. In particular, $d_Q$ satisfies the triangle inequality, i.e. for any 3 trees $T_1, T_2, T_3$ on the same leaf set, $d_Q(T_1, T_3) \leq d_Q(T_1, T_2) + d_Q(T_2, T_3)$. This leads to a factor 2 approximation algorithm for WMQI obtained by simply returning the best tree from the input. Intuitively, the input tree that is the closest to the others cannot be too far from the best solution, which is a median tree in the metric space. See [2] for details.

**Theorem 5** ([2]). The following is a factor 2 approximation algorithm for WMQI: output the tree $T \in \mathcal{T}$ that minimizes $\sum_{T_i \in \mathcal{T}} d_Q(T_i, T)$.

In [2], the authors explain how to compute $d_Q(T_1, T_2)$ in time $O(n^2)$. Therefore the factor 2 approximation can be implemented to run in time $O(k^2n^2)$, by simply computing $d_Q$ between every pair of trees.

Theorem 5 has a direct implication on the approximation guarantees of the ASTRAL algorithm in [20], an implementation of the work from Bryant and Steel [8]. This algorithm finds, in polynomial time, an optimal solution $M$ for a restricted version of WMQI where every bipartition of $M$ is also a bipartition in at least one of the input trees. The solution $T$ returned by the algorithm of Theorem 5 above trivially satisfies this condition. Thus, $M$ is at least as good as $T$, implying the following.

**Corollary 6.** The ASTRAL algorithm is a factor 2 approximation for WMQI.

We do not know whether the factor 2 is tight for the ASTRAL algorithm - we conjecture that ASTRAL can actually achieve a better approximation ratio. As shown in the rest of this section, this would have interesting applications for the approximability of WQC.

Indeed, both WQC and WMQI share the same set of optimal solutions, but the two problems are not necessarily identical in terms of approximability. We show however that WMQI can be used to approximate WQC. As stated earlier, there is a trivial factor 1/3 randomized approximation for WQC: output a random tree $T$. Each quartet of $Q$ has a 1/3 chance of being contained by $T$, and so the expected number of quartets of $Q$ contained by...
$T$ is $|Q|/3 = k(n)/3$ (here $|Q|$ denotes the multiset cardinality). Call this the “random-tree-algorithm”. For the sake of having a deterministic algorithm, we show the following:

Lemma 7. The “random-tree-algorithm” can be derandomized, i.e. there is a deterministic algorithm that, in time $O(kn^2 + n^3)$, finds a tree containing at least $|Q|/3$ quartets from $Q$.

Proof. We derandomize the factor $1/3$ algorithm using the standard method of conditional expectation. For the simplicity of exposition, we will construct a rooted tree $T$ in a top-down manner ($T$ can be unrooted after the construction). Call a rooted tree $T$ internally binary if the only nodes of $T$ that have more than two children have only leaves as children. We start with a fully unresolved internally binary tree $T$ on leaf set $X$ (i.e. $T$ consists of a root whose $n$ children are in bijection with $X$). We then iteratively split each unresolved node $v$ of $T$ into two subtrees so as to maximize the expected number of quartets that $T$ contains. We stop when $T$ is a binary tree.

To describe the algorithm more precisely, suppose that $T$ is an internally binary tree on leaf set $X$, and let $v$ be a node of $T$ with more than 2 children, say $\{v_1, \ldots, v_m\} \subseteq X$ (if no such $v$ exists, then $T$ is binary and we can stop). We split $v$ by first removing $\{v_1, \ldots, v_m\}$ from $T$, adding two children $x$ and $y$ to $v$, and reinserting $v_1, \ldots, v_m$ one after another, each as either a child of $x$ or a child of $y$. We describe how this choice is made. Suppose that for $i \geq 1$, $v_1, \ldots, v_{i-1}$ have been reinserted, resulting in the tree $T_{i-1}$, and that we need to process $v_i$. Denote by $T_{i,x}$ (resp. $T_{i,y}$) the tree obtained by inserting $v_i$ as a child of $x$ (resp. of $y$) in $T_{i-1}$. We then define a random binary tree $T'_{i,x}$ from $T_{i,x}$ as follows: for each $v' \in \{v_{i+1}, \ldots, v_m\}$, reinsert $v'$ as a child of $x$ with probability $1/2$, or as a child of $y$ with probability $1/2$. Then, replace each non-binary node $w$ with children $X'$ by a rooted binary tree on leaf set $X'$ chosen uniformly at random. We define the random binary tree $T'_{i,y}$ from $T_{i,y}$ using the same process.

For a random tree $T'$ obtained by the above process and for $q \in Q$, let $I(q, T')$ be an indicator variable for whether $q \in Q(T')$. That is, $I(q, T') = 1$ if $q \in Q(T')$, and $I(q, T') = 0$ otherwise. Let $I(T') = \sum_{q \in Q} I(q, T') f_Q(q)$. We seek

$$\max_{T' \in \{T'_{i,x}, T'_{i,y}\}} \mathbb{E}[I(T')] = \max_{T' \in \{T'_{i,x}, T'_{i,y}\}} \mathbb{E}\left[\sum_{q \in Q} I(q, T') f_Q(q)\right] = \max_{T' \in \{T'_{i,x}, T'_{i,y}\}} \mathbb{E} I(T') f_Q(q).$$

If $T'_{i,x}$ attains this maximum, we insert $v_i$ below $x$, and otherwise we insert $v_i$ below $y$. After every child $v_i$ of $v$ has been inserted, we process the next non-binary node. This concludes the algorithm description (we shall detail how to compute $\Pr[q \in Q(T')]$ below).

If $T$ is an internally binary tree, by a slight abuse of notation define $\mathbb{E}[I(T)] = \mathbb{E}[I(T')]$, where $T'$ is the random binary tree obtained by replacing each non-binary node of $T$ on leaf set $X'$ by a random binary tree on leaf set $X'$.

Claim 1. Let $T$ be an internally binary tree, and suppose that $\mathbb{E}[I(T)] \geq |Q|/3$. Let $v$ be a non-binary node of $T$, and let $T'_v$ be the tree obtained after splitting $v$ using the above algorithm. Then $\mathbb{E}[I(T'_v)] \geq |Q|/3$.

---

2 Observe that here, $q \in Q$ means that there exists at least one occurrence of $q$ in the multiset $Q$, and so each quartet present in $Q$ is considered once in the summation, independently of $f_Q(q)$.
Let \( \{v_1, \ldots, v_m\} \) be the children of \( v \). To prove the claim, we use induction on the number of processed children of \( v \) to show that after each insertion of a child \( v_i \), the obtained tree \( T_i \in \{T_{i,x}, T_{i,y}\} \) satisfies \( \mathbb{E}[I(T_i)] \geq |Q|/3 \), where \( T_i' \in \{T_{i,x}'\} \) is the random tree corresponding to \( T_i \) obtained from the above process (i.e. reinserting \( v_{i+1}, \ldots, v_m \) randomly under \( x \) or \( y \), and resolving non-binary nodes randomly). This proves the statement since \( T_m = T_v \) (and thus \( \mathbb{E}[I(T_v)] = \mathbb{E}[I(T_m)] = \mathbb{E}[I(T_m')] \geq |Q|/3 \)). As a base case, if \( i = 1 \) it is easy to see that \( T_{1,x}' \) and \( T_{1,y}' \) are identical, and that \( \mathbb{E}[I(T_{1,x})] = \mathbb{E}[I(T_{1,y})] = \mathbb{E}[I(T)] \geq |Q|/3 \). For \( i > 1 \), let \( T_{i-1} \) be the tree obtained after inserting \( v_{i-1} \), and suppose without loss of generality that \( T_i = T_{i-1,x}' \). Because, in \( T_{i-1,x}' \), we insert \( v_i \) below \( x \) or \( y \) each with probability \( \frac{1}{2} \), we have

\[
\mathbb{E}[I(T_{i-1,x}')] = \frac{1}{2} \mathbb{E}[I(T_{i-1,x})|v_i \text{ is a child of } x] + \frac{1}{2} \mathbb{E}[I(T_{i-1,x})|v_i \text{ is a child of } y]
\]

\[
= \frac{1}{2} \left( \mathbb{E}[I(T_{i,x})] + \mathbb{E}[I(T_{i,y})] \right).
\]

By induction, we also have \( \mathbb{E}[I(T_{i-1,x}')] \geq |Q|/3 \). Combined with the above equality, we obtain \( \frac{1}{2} \left( \mathbb{E}[I(T_{i,x}')] + \mathbb{E}[I(T_{i,y}')] \right) \geq |Q|/3 \). This implies that one of \( \mathbb{E}[I(T_{i,x})] \) or \( \mathbb{E}[I(T_{i,y})] \) must be at least \( |Q|/3 \). \( \blacktriangleleft \)

Since the fully unresolved tree \( T \) from which we start satisfies \( \mathbb{E}[I(T)] \geq |Q|/3 \), Claim 1 shows that the algorithm does terminate with a tree containing at least \( |Q|/3 \) quartets from \( Q \). It remains to be show how to compute, when reinserting a node \( v_i \), the expectations for \( T_{i,x}' \) and \( T_{i,y}' \).

In fact, it suffices to be able to compute, for a given quartet \( q = ab|cd \), the probability \( \Pr[q \in Q(T')] \) for \( T' \in \{T_{i,x}', T_{i,y}'\} \). Moreover, if \( \Pr[q \in Q(T_{i,x}')] = \Pr[q \in Q(T_{i,y}')] \), then this probability does not contribute to determining which scenario maximizes expectation, and in this case we do not need to consider \( q \). In particular, if none of \( a, b, c, d \) is equal to \( v_i \), then \( \Pr[q \in Q(T_{i,x}')] = \Pr[q \in Q(T_{i,y}')] \). Therefore, it is enough to consider only quartets in which \( v_i \) is included. We will assume that \( v_i = a \). Moreover, we may assume that two or three of \( \{b, c, d\} \) are children of \( v \) in \( T \) (recall that \( v \) is the parent of \( v_i \) in \( T \)), because otherwise the probability that \( ab|cd \) is in \( T' \) is unaffected by whether \( a \) is a child of \( x \) or \( y \) a child of \( y \).

There are still multiple cases depending on which of \( b, c \) and \( d \) are children of \( v \), or which have been reinserted and have not, but this probability can be easily found algorithmically. Let \( U = \{b, c, d\} \cap \{v_{i+1}, \ldots, v_m\} \), i.e. the leaves in \( \{b, c, d\} \) that have not been reinserted yet in \( T' \). We obtain new trees \( S_1', \ldots, S_h' \) by reinserting, in \( T' \), the members of \( U \) below \( x \) or \( y \) in every possible way – there are only \( 2^{|U|} \leq 8 \) possibilities, so \( h \leq 8 \). Then, for \( 1 \leq j \leq h \) denote by \( S_j'|q \) the tree \( S_j' \) restricted to \( \{a, b, c, d\} \) (i.e. obtained by removing every leaf not in \( \{a, b, c, d\} \), then contracting degree 2 vertices). Note that \( S_j'|q \) may be non-binary. We get

\[
\Pr[q \in Q(T')] = \sum_{j=1}^{h} \frac{1}{h} \Pr[q \in Q(S_j'|q)].
\]

This is because every leaf in \( v_{i+1}, \ldots, v_m \) other than \( b, c, d \) is reinserted independently from the choice for \( b, c, d \), and every non-binary node remaining after the reinsertions is resolved uniformly. The probability \( \Pr[q \in Q(S_j'|q)] \) is straightforward to compute, as only a constant number of cases can occur since \( S_j'|q \) has only 4 leaves. We omit the details.

**Time complexity:** we must first preprocess the input in order to compute \( f_q(q) \) for each quartet \( q \). This takes time \( O(kn^4) \). As for the computation of \( \Pr[q \in Q(T')] \), assume that the lowest common ancestor (lca) of two leaves can be found in constant time. This can be achieved naively by simply storing the lca for each pair of leaves in a table of size \( O(n^2) \), and updating the table in time \( O(n) \) each time a decision on some \( v_i \) is made (this does not hinder the total time complexity of the algorithm, though there are more clever ways to handle
dynamic tree lea queries [11]). Then the restrictions $S'_1|_q, \ldots, S'_h|_q$ can be computed in constant time. It is then straightforward to see that, by the above process, $\Pr[q \in Q(T')]$ can be computed in constant time. Each time a node $v_i$ needs to be reinserted, this probability must be computed for the $O(n^3)$ quartets containing $v_i$. There are $n-1$ splits to be performed, and each split requires inserting $O(n)$ nodes. Thus the “binarization” process takes total time $O(n^5)$, and altogether the derandomization takes time $O(kn^4 + n^5)$.

The above leads to a (deterministic) 1/3- approximation. This can be used to show the following. The proof is similar to that of [9, Theorem 2] and is relegated to Appendix B.3.

**Theorem 8.** If WMQI can be approximated within a factor $\alpha$, then WQC can be approximated within a factor $\beta = \alpha/(3\alpha - 2)$.

Combined with Theorem 5 and letting $\alpha = 2$ in Theorem 8 we get the following.

**Corollary 9.** WQC can be approximated within a factor 1/2 in time $O(k^2n^2 + kn^4 + n^5)$.

## 6 Fixed-parameter tractability of WQC

In this section we describe how, based on previous results on the minimum quartet incompatibility problem on complete sets, WQC can be solved in time $O(4^d + k_2^2 + k_3^2 n + n^4)$. Here $k_2$ and $k_3$ are the number of quadsets that have 2 and 3 dominant quartets, respectively, and $d$ is the number of strictly dominant quartets that we are allowed to reject. The algorithm makes direct use of the Gramm-Niedermeyer algorithm [14], henceforth called the GN algorithm.

The GN algorithm solves the following problem: given a complete set of quartets $Q$, find, if it exists, a complete and compatible set of quartets $Q'$ such that at most $d$ quartets of $Q'$ are not in the input set $Q$ (i.e. $|Q'| \setminus Q \leq d$). This is accomplished by repeatedly applying the following theorem:

**Theorem 10 ([14]).** Let $Q$ be a complete set of quartets. Then $Q$ is compatible if and only if for each set of five taxa $\{a,b,c,d,e\} \subseteq X$, $ab|cd \in Q$ implies $ab|ce \in Q$ or $ae|cd \in Q$.

The idea behind the GN algorithm is as follows: find a set of five taxa $\{a,b,c,d,e\}$ that does not satisfy the condition of Theorem 10, then correct the situation by branching into the four possible choices:

1. remove $ab|cd$ from $Q$ and add $ae|bd$ to $Q$;
2. remove $ab|cd$ from $Q$ and add $ad|be$ to $Q$;
3. remove $\{ac|be,ae|bc\} \cap Q$ from $Q$ and add $ab|ce$ to $Q$;
4. remove $\{ac|de,ad|ce\} \cap Q$ from $Q$ and add $ae|cd$ to $Q$.

The quartets added to $Q$ will not be questioned in the following branchings. With some optimization, this leads to a $O(4^d n + n^4)$ FPT algorithm.

In [14], the authors also note that this algorithm can be extended to sets of quartets $Q$ that contain ambiguous quadsets, i.e. sets $\{a,b,c,d\}$ for which 2 or 3 of the possible quartets on $\{a,b,c,d\}$ are in $Q$. Suppose there are $k_2$ and $k_3$, respectively, quadsets that have 2 and 3 quartets in $Q$. The modified algorithm then, in a first phase, branches into the $2^{k_2}3^{k_3}$ ways of choosing one quartet per such quadset, thereby obtaining a complete set of quartets for each possibility. The GN algorithm is thus applied to the so-obtained complete sets. This yields a $O(2^{k_2} \cdot 3^{k_3} \cdot 4^d n + n^4)$ algorithm.

It is not hard to see that this gives an FPT algorithm for WQC, where the parameter $k_2$ (resp. $k_3$) is the number of quadsets such that 2 (resp. 3) possible quartets appear in the input trees, and $d$ is the number of quartets $ab|cd$ that appear in every input tree, and that
we are allowed to discharge. Note however that, in the consensus setting, there is no reason to believe that \( k_2 \) and \( k_3 \) are low - in fact we believe that \( k_2 + k_3 \) typically takes values in \( \Theta(n^4) \). One reason is that even the slightest amount of noise on a quadset makes it included in the count of either \( k_2 \) or \( k_3 \) (e.g. if \( k - 1 \) trees agree on \( ab|cd \) and only one contains \( ac|bd \)).

The GN algorithm can, however, be used on a more interesting set of parameters. Define \( k'_2 \) (resp. \( k'_3 \)) as the number of quadsets that have exactly 2 (resp. 3) dominant quartets, and let \( d' \) be the number of strictly dominant quartets that we are allowed to discharge. Note however that, in the consensus setting, there is no reason to believe that \( k_2 + k_3 \) is low - in fact we believe that \( k_2 + k_3 \) typically takes values in \( \Theta(n^4) \). One reason is that even the slightest amount of noise on a quadset makes it included in the count of either \( k_2 \) or \( k_3 \) (e.g. if \( k - 1 \) trees agree on \( ab|cd \) and only one contains \( ac|bd \)).

The GN algorithm can, however, be used on a more interesting set of parameters. Define \( k'_2 \) (resp. \( k'_3 \)) as the number of quadsets that have exactly 2 (resp. 3) dominant quartets, and let \( d' \) be the number of strictly dominant quartets that we are allowed to discharge. It is reasonable to believe that, if each tree of the input is close to the true tree \( T^* \), most “true” quartets will appear as strictly dominant in the input, and there should not be too many ambiguous quadsets. There is a very simple algorithm achieving time \( O(4d' + k'_2 + k'_3 n n^3 + n^4) \).

Construct a complete set of quartets \( Q \) as follows: for each quadset \( \{a, b, c, d\} \), choose a dominant quartet on \( \{a, b, c, d\} \) and add it to \( Q \) (if multiple choices are possible, choose arbitrarily). Then, run the GN algorithm on \( Q \) with the following modification: each time a quartet \( q \) is removed from \( Q \) and replaced by another quartet \( q' \), decrement either \( d' \), \( k'_2 \) or \( k'_3 \), depending on whether \( q \) belongs to a quadset with 1, 2 or 3 dominant quartets. It follows that if there exists a complete and compatible set of quartets \( Q' \) such that at most \( d' \) strictly dominant quartets are rejected, then the modified algorithm will find it. It should be noted however that finding such a set \( Q' \) does not guarantee that the corresponding tree is an optimal solution. Indeed, since quartets are weighted, two solutions \( Q' \) and \( Q'' \) may both reject only \( d' \) strictly dominant quartets, yet one has higher weight than the other. However, the correctness of the algorithm follows from the fact that the GN algorithm finds the set of every solution discarding at most \( d' \) dominant quartets - and thus it suffices to pick the solution from this set that has optimal weight.

We finally mention that the FPT algorithms published in [10] are improved versions of the GN algorithm, can also return every solution and thus can be modified in the same manner. These yield FPT algorithms that can solve WQC in time \( O(3.046d' + k'_2 + k'_3 n n^3 + n^4) \) and \( O(2.0162d' + k'_2 + k'_3 n^3 + n^5) \).

7 Conclusion

In this paper, we have shown that the WQC problem is NP-hard, answering a question of [19] and [2]. In the latter, the authors also propose a variant of the problem in which the output tree \( T \) is not required to be binary. In this case, one needs to assign a cost \( p \) to the unresolved quartets. Our reduction can be extended to show that hardness holds for high enough \( p \), but the complexity of the general case remains open. We have also shown that WQC can be approximated within a factor 1/2. One open question is whether the problem admits a PTAS as the related CMQC problem. The fixed-parameter tractability aspects of WQC also deserve further investigation. This would require identifying some structural properties that are present in the consensus setting and that can be used for designing practical exact algorithms. But as we have shown, this might not be an easy task, as many properties which seem reasonable for the consensus setting do not hold.

References

Implications for the Weighted Triplet Consensus problem

For each set of three labels \{a, b, c\}, there are three non-isomorphic\(^3\) rooted binary trees called triplets. They are denoted by \(ab|c\), \(ac|b\) and \(bc|a\), depending on the leaf having the root as father (c, b and a respectively). We say that a tree \(T\) induces or displays the triplet \(ab|c\) if \(\mathcal{L}(T) = \{a, b, c\}\). For a rooted tree \(R\), denote by \(tr(R)\) the set of triplets of \(R\).

When the consensus is sought for rooted trees, the objective is to find a rooted tree \(M\) that induces a maximum number of triplets contained in the input trees. The Weighted Triplet Consensus (WTC) problem is defined as follows.

**Weighted Triplet Consensus (WTC) problem**

**Input:** a set of rooted trees \(\mathcal{R} = \{R_1, \ldots, R_k\}\) such that \(\mathcal{L}(R_1) = \ldots = \mathcal{L}(R_k) = \mathcal{X}\).

**Output:** a binary rooted tree \(M\) with \(\mathcal{L}(M) = \mathcal{X}\) that maximizes \(\sum_{R \in \mathcal{R}} |tr(M) \cap tr(R)|\).

As in the unrooted problem, other versions of WTC where the input trees may have missing species or where the weight of a triplet is not defined w.r.t. a set of trees, are known to be NP-hard [6]. The WTC problem is conjectured to be NP-hard in [2] (we note that a more general version where the output can be non-binary is also conjectured NP-hard).

We give the main idea behind the proof of the hardness of WTC. Let \(\mathcal{T} = \bigcup_{C \in \mathcal{C}} \mathcal{T}(C)\) be the set of unrooted trees constructed in the reduction above. For a tree \(T \in \mathcal{T}\), let \(e\) be the edge separating \(Z\) from the rest of the tree (i.e. by removing \(e\) from \(T\), one connected component is exactly \(Z\)). Obtain a rooted tree \(R\) from \(T\) by rooting \(T\) at \(e\), that is subdivide \(e\), thereby creating a degree 2 vertex which is the root of \(R\). The set of rooted trees \(\mathcal{R}\) is obtained by applying this rooting to every \(T \in \mathcal{T}\) (the \(Z\) subtree could be removed but we keep it here to make the correspondence easier to see).

---

\(^3\) Isomorphism preserving labels and the root node.
Similarly as above, it can be shown that since every input tree is a rooted \((W,Z)\)-caterpillar, then any solution must also have this form. This implies in turn that there exists a linear ordering of \(S\) satisfying \(C\) if and only if there is a solution \(M\) to WTC containing every triplet from the input on 2 or 3 members of \(\mathcal{L}(W)\), every triplet containing at least one member of \(\mathcal{L}(Z)\), plus at least \(4m|W| + 3m|W| (\binom{n-2}{2} + 2(n-2))\) triplets of the form \(wal\) with \(a,b \in S\). This is obtained by defining the notions of in-triplets and out-triplets analogously as in the previous section, but with respect to \(W\) only. That is, in a “\(a < b\)” tree, for \(a,b,c,d \in S, w, v \in \mathcal{L}(W)\) and \(\{c,d\} \neq \{a,b\}, wal\) would be an in-triplet, whereas \(wc|d\) or \(wd|c\) would be out-triplets. One can argue that for a cyclic triple \((a,b,c)\) and the set of trees \(\mathcal{T}((a,b,c))\), an optimal consensus tree can contain \(4|W|\) of the \(6|W|\) possible in-triplets, plus at most half of the \(6m|W| (\binom{n-2}{2} + 2(n-2))\) possible out-triplets. The arguments are essentially the same as the ones given in the hardness proof of WQC, and so we omit the details.

\textbf{Theorem 11.} The Weighted Triplet Consensus problem is NP-hard.

\section{Deferred proofs}

\subsection{Proof of Lemma 3}

Despite the Lemma 3 statement being quite intuitive, it requires a surprising amount of care. We start by a simple proposition that will be needed.

\textbf{Proposition 12.} Let \(X, Y\) be two non-empty sets such that \(Y \not\subseteq X\). Then \(|X| \cdot |Y \setminus X| \geq |Y| - 1\).

\textbf{Proof.} Suppose first that \(X \cap Y = \emptyset\). Then clearly \(|X||Y \setminus X| = |X||Y| \geq |Y| - 1\). Suppose otherwise that \(X \cap Y \neq \emptyset\), and denote \(X' = X \cap Y\). Then \(|Y \setminus X| = |Y| - |X'|\) and since \(Y \not\subseteq X\), we must have \(|Y| \geq |X'| + 1\). We also have \(|X||Y \setminus X| = |X||(Y - |X'|) \geq |X'||(|Y| - |X'|)\); we claim the latter term to be at least \(|Y| - 1\). Let us assume for contradiction that \(|X'||(|Y| - |X'|) < |Y| - 1\). If \(|X'| = 1\), this is clearly impossible, so assume \(|X'| > 1\). Then we get \(|X'|||Y| - |X'| < |X'|^2 - 1\) leading to \(|Y| < \frac{|X'|^2 - 1}{|X'| - 1} = |X'| + 1\), contradicting \(|Y| \geq |X'| + 1\).

Before proceeding, we must introduce the notion of a rooted subtree of a binary unrooted tree \(T\). Note that by removing an edge \(e = \{u, v\}\) of \(T\), we obtain two disjoint rooted subtrees \(T_u\) and \(T_v\), respectively rooted at \(u\) and \(v\). Call \(T'\) a rooted subtree of \(T\) if \(T'\) is a rooted tree that can be obtained by removing an edge of \(T\). For \(X \subseteq \mathcal{L}(T)\), a rooted subtree for \(X\) is a rooted subtree \(T'\) of \(T\) such that \(X \subseteq \mathcal{L}(T')\). We denote by \(T[X]\) the rooted subtree for \(X\) that contains a minimum number of leaves (if there are multiple choices, choose \(T[X]\) arbitrarily among the possible choices). Note that \(T[X]\) may contain leaves other than \(X\).

We now prove that any optimal solution to \(T\) as constructed in our reduction must be a \((W,Z)\)-augmented caterpillar. Suppose that \(M\) is an optimal solution to \(T\), and that \(M\) is not a \((W,Z)\)-augmented caterpillar. Denote \(M_W = M[\mathcal{L}(W)]\) and \(M_Z = M[\mathcal{L}(Z)]\). If \(M\) is a \((W', Z')\)-augmented caterpillar \((W'|T_1| \ldots |T_k|Z')\) for some trees \(W', Z'\) with \(\mathcal{L}(W') = \mathcal{L}(W)\) and \(\mathcal{L}(Z') = \mathcal{L}(Z)\), it is not hard to see that \(M' = (W'|T_1| \ldots |T_k|Z')\) is a better solution than \(M\), a contradiction. Thus, \(M\) is not such a caterpillar, and this implies that either \(\mathcal{L}(M_W) \neq \mathcal{L}(W)\) or \(\mathcal{L}(M_Z) \neq \mathcal{L}(Z)\) (or both). That is, the rooted subtrees containing \(\mathcal{L}(W)\) and/or \(\mathcal{L}(Z)\) have “outsider” leaves. Suppose first that \(\mathcal{L}(M_W) \neq \mathcal{L}(W)\) holds. Then there exists a node \(x\) with children \(x_1\) and \(x_r\) in \(M_W\) such that all leaves \(X_l\) below \(x_l\) are in \(\mathcal{L}(W)\) with \(\mathcal{L}(W) \subset X_l\) (otherwise \(M_W = M[\mathcal{L}(W)]\) would be chosen incorrectly), and no leaf \(X_r\)
On the Weighted Quartet Consensus Problem

below $x_r$ belongs to $\mathcal{L}(W)$ (this can be seen by observing that the minimal node $x$ of $M_W$ having leaves both in $W$ and not in $W$ has this property).

We claim that $\mathcal{L}(Z) \not\subseteq X_r$. Suppose otherwise that $\mathcal{L}(Z) \subseteq X_r$. Then $|X_r| \geq |Z|$ and so $|M_W| \geq |W| + |Z|$. However in $M$, by removing the $xx_r$ edge we obtain two rooted trees, one of which is a rooted subtree for $\mathcal{L}(W)$. Moreover, this subtree has at most $|W| + |S| < |W| + |Z|$ leaves, which contradicts the minimality of $M_W = M[\mathcal{L}(W)]$. We deduce that $\mathcal{L}(Z)$ is not a subset of $X_r$.

Now, observe that $M$ contains the quartet $w_1y|w_2z$ for each $w_1 \in X_l, y \in X_r, w_2 \in \mathcal{L}(W) \setminus X_l, z \in \mathcal{L}(Z) \setminus X_r$. There are at least $|X_l||X_r|(|\mathcal{L}(W) \setminus X_l|)(|\mathcal{L}(Z) \setminus X_r|) \geq (|W| - 1)(|Z| - 1)$ such quartets (the inequality is obtained by applying Proposition 12 to $|X_l| \cdot |\mathcal{L}(W) \setminus X_l|$ and $|X_r| \cdot |\mathcal{L}(Z) \setminus Z|$). Moreover, each input tree of $\mathcal{T}$ contains the quartet $w_1w_2|yz$ instead, and hence in total in $\mathcal{T}$ there are at least $6m(|W| - 1)(|Z| - 1)$ quartets of the form $w_1w_2|yz$ that $M$ does not contain. In the same manner, if the case $\mathcal{L}(M_Z) \neq \mathcal{L}(Z)$ holds, there are at most $6m(|W| - 1)(|Z| - 1)$ quartets of the form $z_1z_2|yw$ that $M$ does not contain, where here $z_1, z_2 \in \mathcal{L}(Z), y \notin \mathcal{L}(Z), w \in \mathcal{L}(W)$.

Now, let $\rho(M)$ be the number of quartets that $M$ contains from $\bigcup_{T \in \mathcal{T}} Q(T)$ that have the form $wx|yz$, where $w \in \mathcal{L}(W), z \in \mathcal{L}(Z), x, y \in S$. Formally,

$$\rho(M) = \sum_{wx|yz \in Q(M)} f(wx|yz) \sum_{x, y \in S} \sum_{w \in \mathcal{L}(W)} \sum_{z \in \mathcal{L}(Z)}$$

where $f(wx|yz)$ denotes the number of trees of $\mathcal{T}$ that contain the $wx|yz$ quartet. For a given $u \in \mathcal{L}(W) \cup \mathcal{L}(Z)$, let $\rho(M, u)$ denote the number of quartets counted in $\rho(M)$ that contain $u$. Formally, if $w \in \mathcal{L}(W)$, we have

$$\rho(M, w) = \sum_{wx|yz \in Q(M)} f(wx|yz) \sum_{x, y \in S} \sum_{z \in \mathcal{L}(Z)}$$

The definition of $\rho(M, z)$ is the same for $z \in \mathcal{L}(Z)$, except that $z$ gets fixed instead of $w$ in the summation. Notice that $\rho(M) = \sum_{u \in \mathcal{L}(W)} \rho(M, u) = \sum_{z \in \mathcal{L}(Z)} \rho(M, z)$. Let $w^* = \arg\max_{w \in \mathcal{L}(W)} \{\rho(M, w)\}$. We obtain an alternative solution $M'$ from $M$ in the following manner: remove all leaves of $\mathcal{L}(W) \setminus \{w^*\}$ from $M$, delete the degree 2 nodes, and replace $w^*$ by the $W$ tree. Note that if $w^*|yz$ is a quartet of $M$, then $wx|yz$ is a quartet of $M'$ for all $w \in \mathcal{L}(W)$, and so $\rho(M', w) \geq \rho(M, w)$ for all such $w$ by the choice of $w^*$. Consequently, $\rho(M') \geq \rho(M)$. We repeat the same operation on $M'$ for the $Z$ tree and obtain our final tree $M^*$. That is, we find $z^* = \arg\max_{z \in \mathcal{L}(Z)} \{\rho(M', z)\}$, and replace $z^*$ by the $Z$ tree. As above, we obtain $\rho(M^*) \geq \rho(M')$. Since $M^*$ has $W$ and $Z$ as rooted subtrees, it follows that $M^*$ is a $(W, Z)$-augmented caterpillar.

We argue that $M^*$ contains more quartets from the input trees than $M$. First observe that the quartets on which $M$ and $M^*$ differ must contain a member of $\mathcal{L}(W) \cup \mathcal{L}(Z)$, since only these leaves switched position. The tree $M^*$ contains every quartet of $\bigcup_{T \in \mathcal{T}} Q(T)$ that have at least two members of $\mathcal{L}(W)$, or two members of $\mathcal{L}(Z)$. This includes the aforementioned (at least) $6m(|W| - 1)(|Z| - 1)$ quartets of the form $w_1w_2|yz$ or $z_1z_2|yw$ that $M$ does not contain. As for the quartets that contain one member of $\mathcal{L}(W)$ and one member of $\mathcal{L}(Z)$, $M^*$ contains at least as many such quartets as $M$ since in $\bigcup_{T \in \mathcal{T}} Q(T)$, these quartets are all of the form $wx|yz$, and we have $\rho(M^*) \geq \rho(M)$. Finally, each tree of $\mathcal{T}$ has at most $(|W| + |Z|)n^3$ quartets that have exactly one member of $\mathcal{L}(W) \cup \mathcal{L}(Z)$. Thus
Figure 1 An instance of WQC such that the optimal solution (the third tree on the first row) contains no strictly dominant quartet. The numbers correspond to the number of times that each tree appears in the input.

Figure 2 The first four trees form an instance of WQC in which every tree contains \(ab|cd\). The rightmost tree is the unique optimal solution to the WQC instance (every possible solution was verified computationally).

at most \(6n(|W| + |Z|)n^3\) quartets of this type are contained by \(M\) and not contained by \(M^*\), but since this is smaller than \(6n(|W| - 1)(|Z| - 1)\) for our choice of \(|W|\) and \(|Z|\), \(M^*\) contains more quartets from the input than \(M\).

B.2 Proofs of Section 4

Conjecture 1 is disproved by Theorem 13, and Conjecture 3 by Theorem 14, which implies that Conjectures 2 and 4 are also false; finally Conjecture 5 is disproved by Theorem 15.

**Theorem 13.** There exists an instance of WQC such that every optimal solution contains none of the strictly dominant quartets.

Figure 1 shows an instance of WQC demonstrating Theorem 13. In this instance, for every quadset \(S\), there is a strictly dominant quartet appearing 17 times, whereas the second-most and third-most quartets appear in 16 and 11 trees, respectively. For example, \(f(ac|bd) = 17, f(ad|bc) = 16\) and \(f(ab|cd) = 11\). One can check that the best tree is the third one on the top row (the \(ac|bc\) with \(d\) grafted on the middle branch). Call this tree \(T^*\). For every quadset \(S\), \(T^*\) contains the second-most frequent quartet on \(S\). The reason why \(T^*\) is optimal is that, in the particular instance of Figure 1, any other tree \(T\) that contains a strictly dominant quartet for some quadset \(S\) must also contain a least frequent quartet on
some other quadset $S'$. Hence, as there are 5 quadsets, $T$ contains at most $4 \cdot 17 + 11 = 79$ quartets from the input, whereas $T^*$ contains $5 \cdot 16 = 80$. Note that this example consists of trees on only 5 leaves. We do not know if such instances exist for any $n > 5$ leaves.

▶ **Theorem 14.** There exists an instance of WQC such that there is a quartet $q$ that appears in every input tree, but $q$ is not a quartet of any optimal solution.

Figure 2 shows an instance of WQC proving Theorem 14. Each input tree contains the $ab|cd$ quartet, whereas the optimal solution, which is unique, does not. The rightmost tree contains 180 quartets from the input multiset $Q$, whereas any other tree has at most 176.

Finally, we note that the main interest behind Conjecture 5 is the following: if it holds, in cases where the set $F$ of strictly least-frequent quartets is complete we could tell in polynomial time – using results of [8] – whether there is a tree $T^*$ that contains no quartet from $F$. Conjecture 5 could then lead to interesting approximations or FPT algorithms. However, least-frequent quartets cannot be excluded automatically.

▶ **Theorem 15.** There exists an instance of WQC such that every optimal solution contains a strictly least-frequent quartet, even if there exists a tree $T^*$ with no such quartet.

The instance corresponding to Theorem 15 is obtained from the instance shown in Figure 1, by removing all occurrences of the third tree on the top row (i.e. this tree now appears 0 times instead of 3 times). The second-most frequent quartets now appear 13 times each, and so the tree $T^*$ that contains all these quartets has a total weight of $5 \cdot 13 = 65$. However, there are trees with a total weight of 75, which are optimal (for instance, the tree of cardinality 9 in the figure). Each such tree contains a strictly dominant quartet, and as mentioned before, also a strictly least-frequent quartet.

B.3 Proof of Theorem 8

Let $N := k\binom{\frac{n}{4}}{2}$, i.e. the total number of quartets in $Q$, let $p$ be the maximum number of quartets that can be preserved from $Q$ for compatibility, and let $d$ be the minimum number of quartets to discard from $Q$ in order to attain compatibility (here $p$ and $d$ refer to multiset cardinalities). Note that $d = N - p$. We show that taking the best tree between the one obtained from the factor $\alpha$ algorithm for WMQI and the one obtained from the “random-tree-algorithm” achieves a factor $\beta$ for WQC. Suppose first that $p \leq \frac{N}{3\beta}$. By Lemma 7, the “random-tree-algorithm” yields a tree containing at least $\frac{|Q|}{3} = \frac{N}{3}$ quartets from $Q$, and since $\frac{N}{3} = \beta \frac{N}{3\beta} \geq \beta p$, it yields a solution to WQC within a factor $\beta$ from optimal. Thus we may assume that $p > \frac{N}{(3\beta)} = \frac{N(3\alpha - 2)}{(3\alpha)}$. Since we have an $\alpha$ approximation for WMQI, we may obtain a solution discarding at most $\alpha d = \alpha(N - p)$ quartets. This solution preserves at least $N - (\alpha(N - p)) = \alpha p + (1 - \alpha)N$ quartets from $Q$. We claim that this attains a factor $\beta$ approximation. Suppose instead that $\alpha p + (1 - \alpha)N < \beta p$. Then $p < \frac{(\alpha - 1)N}{(\alpha - \beta)}$ which, with a little work, yields $p < \frac{N(3\alpha - 2)}{(3\alpha)}$, contradicting our assumption on $p$. Thus, the WMQI approximation preserves at least $\beta p$ quartets.
Optimal Omnitig Listing for Safe and Complete Contig Assembly

Abstract

Genome assembly is the problem of reconstructing a genome sequence from a set of reads from a sequencing experiment. Typical formulations of the assembly problem admit in practice many genomic reconstructions, and actual genome assemblers usually output contigs, namely substrings that are promised to occur in the genome. To bridge the theory and practice, Tomescu and Medvedev [RECOMB 2016] reformulated contig assembly as finding all substrings common to all genomic reconstructions. They also gave a characterization of those walks (omnitigs) that are common to all closed edge-covering walks of a (directed) graph, a typical notion of genomic reconstruction. An algorithm for listing all maximal omnitigs was also proposed, by launching an exhaustive visit from every edge.

In this paper, we prove new insights about the structure of omnitigs and solve several open questions about them. We combine these to achieve an $O(nm)$-time algorithm for outputting all the maximal omnitigs of a graph (with $n$ nodes and $m$ edges). This is also optimal, as we show families of graphs whose total omnitig length is $\Omega(nm)$. We implement this algorithm and show that it is 9-12 times faster in practice than the one of Tomescu and Medvedev [RECOMB 2016].

1 Introduction

Genome assembly is the problem of reconstructing a genome sequence from a set of reads from a sequencing experiment. It is one of the oldest problems in bioinformatics, but many challenges remain. For example, assemblers for novel sequence technologies such as Oxford nanopore are still only in development. Assembly of heterogeneous tumor data is also a challenge. Many of these challenges can be met by building on top of existing assembly algorithms. However, recent directions to improve the theoretical underpinning of assembly have the potential to improve assembly across a wide breadth of scenarios.

Genome graphs have been the basis of most assembly algorithms. There is the edge-centric de Bruijn graph [2, 15], where every \( k \)-mer (string of length \( k \)) of the reads becomes a node and every \( (k + 1) \)-mer of the reads becomes an edge, or the node-centric de Bruijn graph, where the nodes are the same but the edges are \( (k - 1) \)-overlaps between nodes. In a string graph, every read becomes a node and large enough non-transitive overlaps between reads are represented as edges [11, 16]. In a recent paper [17], these graphs were unified under the “genome graph” model. Theoretical formulations of the assembly problem define what a genome reconstruction is: typically, this is a walk in a genome graph, subject to some constraints. For example, a genome reconstruction could be a closed (i.e., circular) walk covering every edge of the genome graph exactly once [14, 8, 13] (to be called edge-covering in the ongoing), or a closed Eulerian walk [9, 10, 12, 5].

However, algorithms to find an entire genome reconstruction are rarely implemented in practice, because there is usually more than one valid genome reconstruction. When assemblers have no way to distinguish different reconstructions, they instead output contigs, which are stretches of DNA that are assumed to be in the genome. To bridge theory and practice, Tomescu and Medvedev proposed in [17] an alternative formulation of the contig assembly problem. A string is considered safe if it is guaranteed to occur in every valid genome reconstruction. A contig assembly algorithm should ideally be safe (i.e., only outputting safe strings) and complete (i.e., every safe string should be output by the algorithm).

Previous work. The notion of a safe and complete algorithm embodies several previous results. Contig assembly was first approached by finding unitigs [6], namely those paths whose internal nodes have in- and out-degree one. Later, some generalizations of unitigs have been considered. For example, [15] considered paths whose internal nodes have out-degree one, with no restriction on their in-degree: [10, 4, 7] considered the unitigs of a genome graph simplified with the so-called Y-to-V transformation (we further discuss this at the end of Section 4). Although no underlying notion of genomic reconstruction was explicit in these studies, it can be shown that the resulting paths are safe for closed edge-covering walks. However, as [17] notices, such approaches do not find all the safe strings. Other studies have indeed given safe and complete algorithms for some reconstruction notions. Nagarajan and Pop [12] attribute to [18] the characterization of the walks common to all closed Eulerian walks. For edge-weighted genome graphs, [12] claims that a simple algorithm exists for finding all those walks common to all shortest closed edge-covering walks.

Tomescu and Medvedev [17] considered the genomic reconstruction notion of a closed edge-covering walk. This model is strictly more general than the above two ones, and thus safe strings for it are also safe for them. Moreover, it is also more realistic, because the Eulerian notion assumes that all positions in the genome are sequenced exactly the same number of times, while the minimality criterion from other notion may over-collapse repeated regions. However, it still assumes that the reads are error-free, single-stranded, come from a circular genome, and every position in the genome appears in some read.
In [17] a characterization of those walks common to all such genomic reconstructions was given. These walks were called omnitigs (see Definition 1), and an algorithm for finding all maximal omnitigs was presented. We refer to [17] for further details on the practical merits of omnitigs, as opposed to e.g., unitigs. The asymptotic running time of this algorithm was not fully analyzed in [17] except to say it was polynomial time. However, it is based on launching an exhaustive visit from every edge of the graph, and extending all such possible walks as long as they are omnitigs. Its running time remained several orders of magnitude slower than finding unitigs, and improving it was recognized as an important open problem.

Contributions and approach of this paper. The main result of this paper is an algorithm (Algorithm 3) running in time $O(n m)$ for outputting all maximal omnitigs of a graph ($m$ is the number of edges, $n$ is the number of nodes, and in this paper all graphs are directed). This algorithm is also optimal, in the sense that there are families of graphs for which the total length of their omnitigs is $\Omega(n m)$ (see e.g., Figure 4).

This algorithm is based on three insights.

1. A structural result connecting branches of a graph (i.e., edges whose source node has out-degree at least two) with left-maximal omnitigs (Theorem 8). In particular, there can be only one left-maximal omnitig ending with a given branch, and the structure of such omnitigs is almost fully characterizable. This also implies that the number of maximal omnitigs is at most $m$ and their individual lengths are bounded by $3n - 1$. We also give families of graphs that achieve these upper bounds, showing that they are tight. Previously, only an upper bound of $nm$ was known on the number of maximal omnitigs and an upper bound of $nm$ on their lengths [17]. This is encouraging also from a practical point of view, because the popular (maximal) unitigs have the same tight asymptotic bounds on their number and individual length (but not on their total length, which is $m$).

2. A partial order between branches, based on whether or not they are connected by “simple” omnitigs (Definition 13), which we prove to be acyclic. This allows us to reuse computation when recursively computing the left-maximal omnitig ending with a given branch.

3. A connection between omnitigs and strong bridges of a graph (i.e., those edges whose removal disrupts strong connectivity [3]). In particular, omnitigs that do not start with a strong bridge are easy to find (Lemma 17). Since there are at most $O(n)$ strong bridges in a graph, this implies that also the number of hard cases is $O(n)$, and not $O(m)$.

We also implement the new algorithm, and show in Section 5 that it is 9-12 times faster in practice than the one of [17]. Finally, at the end of Section 4 we demonstrate that the Y-to-V transformation, used as pre-processing step in the implementation of [17] to simplify the input, can result in shorter maximal omnitigs. This transformation is a well-known method (e.g. [10, 4, 7]) for reducing the genome graph, maintaining the property that its unitigs spell safe strings.

2 Background and notation

In this paper, a graph is a tuple $G = (V, E, s, t)$, where $V$ is a finite set of nodes, $E$ is a finite set of edges, and $s, t: E \rightarrow V$ assign to each edge $e \in E$ its source node $s(e)$ and its destination node $t(e)$. Parallel edges and self-loops are allowed. We say that an edge $e$ goes from $s(e)$ to $t(e)$. The reverse graph of $G$ is defined as $G^R = (V, E, t, s)$.

A walk on $G$ is a sequence $w = (v_0, e_1, v_1, e_2, \ldots, e_{\ell}, v_\ell)$, $\ell \geq 0$, where $v_0, v_1, \ldots, v_\ell \in V$ are nodes and each $e_i$ is an edge from $v_{i-1}$ to $v_i$. We say that $w$ goes from $s(w) = v_0$ to $t(w) = v_\ell$ and has length $|w| = \ell$. A walk $w$ is called empty if $|w| = 0$, and non-empty
If there is a path (or, equivalently, a walk) from any node to any other node, a graph is connected. A univocal walk is a walk whose nodes $v_0, v_1, \ldots, v_t$ are all distinct, except that $v_t = v_0$ is allowed (in which case we have either a closed or an empty path). A graph is strongly connected if there is a path (or, equivalently, a walk) from any node to any other node.

In the rest of this paper, a strongly connected graph $G = (V,E,s,t)$ is given, with $|V| = n$ and $|E| = m \geq n$. We adopt the following conventions. Letters $u,v$ denote nodes, letters $e,f,g,h$ denote edges, which are identified with the corresponding length-1 walks, letters $p,q,r$ denote paths, and letters $w,x,y,z$ denote generic walks (each letter possibly with subscripts or superscripts). Juxtaposition $ww'$ denotes the concatenation of walks $w$ and $w'$, where $t(w) = s(w')$ is implicitly assumed. We start from the following definition of omnitigs offered in [17].

**Definition 1 (Omnitig).** A non-empty walk $w = e_1 \cdots e_t$ is an omnitig if, for every $1 \leq i < j \leq t$, there is no non-empty path from $s(e_j)$ to $t(e_i)$, with first edge different from $e_j$, and last edge different from $e_i$.

The main result from [17] is that those walks that are sub-walks of all closed edge-covering walks of a strongly connected graph are precisely its omnitigs. Clearly every edge is an omnitig and any proper subwalk of an omnitig is an omnitig. Figure 1 illustrates examples of walks that are not omnitigs. An omnitig $w$ is right-maximal (resp., left-maximal) if there is no walk $we$ (resp., $ew$) which is an omnitig. An omnitig is maximal if it is both left- and right-maximal. We note that in [17] two types of omnitigs were considered, depending on the genome model used. Here, we use omnitigs to refer the edge-centric omnitigs from [17].

### 3 Structure of maximal omnitigs

In this section we prove some structural properties of maximal omnitigs. To better understand the ways in which omnitigs might possibly overlap, we propose the notion of branch and univocal walk. A node $u$ is called branching if its out-degree is more than one. In this case, any edge $e$ with $s(e) = u$ is called a branch, and any two distinct edges $e \neq e'$ with $s(e) = s(e') = u$ are called siblings. The set of all branches is denoted by $B \subseteq E$. An edge is called an $R$-branch if it is a branch in $G^R$. A walk is called univocal if none of its edges is a branch and $R$-univocal if none of its edges is an $R$-branch.

We start by showing some facts about branches and univocal walks.

**Lemma 2.** If $G$ contains at least a branch, then every univocal walk is an open path.
Proof. A minimal counterexample is a univocal closed path $p$. Since every path from $s(p)$ is a prefix of $p$, and $G$ is strongly connected, then $p$ contains every node in the graph, and there are no branches.

Lemma 3. If $w$ is an omnitig and $q$ is a univocal path from $t(w)$, then $wq$ is an omnitig.

Proof. Let $p$ be a path certifying that $wq$ is not an omnitig by Definition 1. If $s(p)$ is a node of $q$, then a whole suffix of $q$ is a prefix of $p$, since $q$ is univocal; in this way, the property that the first edge of $p$ differs from $e_j$ would be contradicted. Therefore $s(p)$ is a node of $w$, but then $p$ is a path actually certifying that $w$ is not an omnitig, again a contradiction.

Lemma 4. Every left-maximal omnitig contains a branch.

Proof. Let $w$ be a counterexample, i.e., a left-maximal omnitig which is univocal. Let $e$ be any edge with $t(e) = s(w)$ (at least one exists since $G$ is strongly connected). The edge $e$ is an omnitig, and thus by Lemma 3 $ew$ is an omnitig, violating the left-maximality of $w$.

The crucial observation underlying our algorithm is that any omnitig containing a branch can be extended in an unique way to the left to obtain a left-maximal omnitig. This is expressed in Theorem 8 below. To prove Theorem 8, we need the following lemmas.

Lemma 5. Let $fqe$ be an omnitig where $q$ is an open path and $e$ is a branch. Take any sibling $e'$ of $e$ and a closed path $e'p$ starting with $e'$. Then, $fqe$ is a suffix of $e'p$.

Proof. Let $fqe$ be a minimal counterexample. Then, $fqe$ and $qe$ are both omnitigs, and by minimality $q$ is a suffix of $e'p$, whereas $fq$ is not. Since $q$ is an open path, then $q \neq e'$, so $q$ is actually a suffix of $p$. Thus we can regard $e'p$ as obtained by concatenating its suffix $q$ to its remaining prefix $r$, i.e., $e'p = rq$. Here, $r$ is a non-empty path and fulfills all conditions stated in Definition 1: it starts with $e' \neq e$, and ends with an edge $f' \neq f$ (otherwise $fq$ would be a suffix of $rq = e'p$). This shows that $fqe$ is not an omnitig: a contradiction.

Lemma 6. Let $e'pe$ be a walk where $e$ and $e'$ are siblings and $e'p$ is a closed path. Then, $e'pe$ is an omnitig iff $p$ is univocal and $e'$ is the only sibling of $e$.

Proof. ($\Longleftarrow$) The only path satisfying Definition 1 must start with $e'$, and hence be a prefix of $e'p$. ($\Longrightarrow$). First we show that $e'$ is the only sibling of $e$. Let $e''$ be any sibling of $e$, and take any closed path $e''p'$. Then, $e'p$ is a suffix of $e''p'$ by Lemma 5. Being both closed paths, we have $e'p = e''p'$ and in particular $e'' = e'$.

We now prove that $p$ is univocal. Assume not, and write $p = qfr$ where $f$ is any branch. Let $f'$ be a sibling of $f$, and $f'p'$ a closed path. Clearly, $s(f') = s(f) \neq e$, hence $f'$ does not appear in the closed path $e'p = e'qfr$. Let $q'$ be the shortest prefix of $p'$ where $t(q')$ is a node of $p$. Observe that $q'$ exists since $t(p') = s(f') = s(f)$ is a node of $p$. Moreover, the last edge of $q'$, if any, does not appear in $e'p$. Notice that $t(q')$ is either a node of $q$ or a node of $r$. If $t(q')$ is a node of $q$, then the path $f'q'$ shows that $e'q'f$ is not an omnitig. Otherwise, if $t(q')$ is a node of $r$, then the path $e'q'f'q'$ shows that $fre$ is not an omnitig. In either case $e'pe = e'qfr$ is not an omnitig: a contradiction.

Lemma 7. There is no omnitig of the form $fqrqe$ where $qr$ is a closed path, $r$ is non-empty, $e$ is a branch, and $f$ is an $R$-branch.

Proof. Assume for a contradiction that $fqrqe$ is an omnitig violating the claim of the lemma. Let $e'$ be the first edge of $r$. We will prove that $e' \neq e$. Write $r = e'r'$ and observe that $r'q$ is an open path, so $e'r'qe$ satisfies the hypothesis of Lemma 5. Let $e'' \neq e$ be a sibling of $e$,
and $e''p$ a closed path. Then, by Lemma 5, $e' r' q$ is a suffix of $e''p$. In fact, since both $e' r' q$ and $e''p$ are closed paths, then $e' r' q = e''p$ and $e' = e'' = e$, as claimed.

The very same argument applies on the reverse graph, since the notion of omnitig is symmetric, as well as the statement of the lemma. Therefore, also the last edge $f'$ of $r$ is distinct from $f$. Now, $r$ is a non-empty path with first edge $e' \neq e$ and last edge $f' \neq f$. Hence, $r$ satisfies the conditions of Definition 1, showing that $fqrqe$ is not an omnitig. ▷

► Theorem 8. There exists a unique left-maximal omnitig $we$, ending with a given branch $e$.

Moreover, for any sibling $e'$ of $e$ and a closed path $e'p$, either:
- $we = p'e'pe$, where $p'$ is the longest $R$-univocal path to $s(e)$, or
- $we$ is a suffix of $pe$,
where the first case occurs iff $e'$ is the only sibling of $e$ and $p$ is univocal.

Proof. Consider any omnitig $we$. We show that $we$ is either a suffix of $pe$ or of the form $we = p''e'pe$, where $p''$ is an $R$-univocal path. This suffices to show that there is a unique left-maximal omnitig $we$, and that one of the two cases occurs.

If $w$ is an open path then $we$ is a suffix of $pe$ by Lemma 5. Otherwise, take the shortest suffix $e''p$ of $w$ which is not an open path. Since $p$ is an open path ($e''p$ is the shortest suffix of $w$ which is not), then $e'' = e'$ by Lemma 5.

Hence, a minimal counterexample for our claim is an omnitig of the form $we = fqrepe$ where $q$ is $R$-univocal (hence an open path by Lemma 2 applied to the reversed graph) and $f$ is an $R$-branch. Since $t(q) = t(p)$ and $q$ is $R$-univocal, then $q$ is a suffix of $e'p$. In fact, $q$ is a suffix of $p$, since it is open. Hence, we can write $e'p = rq$, where $r$ is non empty, and $we = fqrqe$, violating Lemma 7.

Finally, the conditions in which the first case occurs are stated in Lemma 6, noticing that $p'e'pe$ is an omnitig iff $e'pe$ is an omnitig, by Lemma 3 applied in the reverse graph. ▷

► Corollary 9. There are at most $m$ maximal omnitigs.

Proof. Any maximal omnitig has a branch by Lemma 4; hence it has the form $w = w'cr$, where $e$ is its last branch and $r$ is univocal. By Theorem 8, $w'$ is uniquely determined by $e$, and, by Lemma 3, $r$ is the longest univocal path from $t(e)$, also uniquely determined by $e$. In conclusion, every omnitig has a last branch and every branch is the last branch of at most one maximal omnitig. ▷

► Corollary 10. Every maximal omnitig traverses any node at most three times, and thus has length at most $3n - 1$.  

![Figure 2](Image) Example of graphs where the two cases of Theorem 8 occur, for $p = g_1g_2f_1f_2$ and $p' = f_1f_2$. In the first case (left), $p$ is univocal and the left-maximal omnitig is $we = p'e'pe = f_1f_2e'g_1g_2f_1f_2e$. In the second case (right) $p$ is not univocal due to the edge $f_2'$, and the left-maximal omnitig is $we = g_1g_2f_1f_2e$. Omnitigs $we$ are shown in red and have solid edges.
We start by considering a procedure \( \text{LongestSuffix} \) that takes an omnitig \( w' \) and an edge \( e \) with \( s(e) = t(w') \), and computes the longest suffix of \( w = w'e \) that is still an omnitig. A pseudo-code for such a procedure is shown in Algorithm 1, and it is an adaptation of the ideas given in [17].

**Lemma 12.** The function \( \text{LongestSuffix} \) can be implemented in \( O(m) \).

The strategy of our algorithm is to first pick a branch \( e \), since by Lemma 4 every maximal omnitig contains one, and then construct the only left-maximal omnitig ending with \( e \), according to Theorem 8. To this end, we may need to compute the longest suffix of \( e'p \) which is an omnitig; however, this could require quadratic time to output a single left-maximal omnitig. Instead, we show that it is possible to recycle the computational effort among different branches, in order to pay linear time per-branch. We introduce the following notion of order between branches.

**Definition 13.** For any two distinct non-sibling branches \( e, f \in B \), write \( f \prec e \) if there exists an omnitig \( fpe \) where \( p \) is univocal.

**Proof.** Any maximal omnitig has the form \( w = w'er \) where \( e \) is its last branch. By Theorem 8, either \( w' \) is an open path, or \( w = p'e'p' \) where \( p', p, r \) are univocal, and hence open paths by Lemma 2. Consider that open paths visit each node at most once.

**Corollary 11.** The total length of maximal omnitis is \( O(nm) \).

In a complete graph with node set \( V \), \( |V| \geq 3 \), and edge set \( V \times V \) every single edge is a maximal omnitig, hence the bound given in Corollary 9 is tight. Figures 3 and 4 demonstrate graph families showing that the bounds of Corollary 10 and Corollary 11 are also tight. That is, they contain maximal omnitis of length \( 3n - 1 \), and the total length of the maximal omnitis can be \( \Omega(nm) \).

**4 The algorithm**

We start by considering a procedure \( \text{LongestSuffix} \) that takes an omnitig \( w' \) and an edge \( e \) with \( s(e) = t(w') \), and computes the longest suffix of \( w = w'e \) that is still an omnitig. A pseudo-code for such a procedure is shown in Algorithm 1, and it is an adaptation of the ideas given in [17].

**Lemma 12.** The function \( \text{LongestSuffix} \) can be implemented in \( O(m) \).

The strategy of our algorithm is to first pick a branch \( e \), since by Lemma 4 every maximal omnitig contains one, and then construct the only left-maximal omnitig ending with \( e \), according to Theorem 8. To this end, we may need to compute the longest suffix of \( e'p \) which is an omnitig; however, this could require quadratic time to output a single left-maximal omnitig. Instead, we show that it is possible to recycle the computational effort among different branches, in order to pay linear time per-branch. We introduce the following notion of order between branches.

**Definition 13.** For any two distinct non-sibling branches \( e, f \in B \), write \( f \prec e \) if there exists an omnitig \( fpe \) where \( p \) is univocal.
Algorithm 1: Function LongestSuffix.

1 Function LongestSuffix(w)

Input: A non-empty walk \( w = w'e \) where \( w' \) is an omnitig and \( e \) is a branch.

Returns: The longest suffix of \( w \) which is an omnitig.

2 Denote \( w = w'e = f_1 \cdots f_\ell e \).

3 Compute the set \( S_e \subseteq V \) of nodes reachable from \( s(e) \) without using \( e \).

4 Let \( \hat{i} \) be the largest index \( i \in \{1, \ldots, \ell\} \) such that there exists an edge \( g /\notin \{e, f_i\} \) with \( s(g) \in S_e \) and \( t(g) = t(f_i) \), taking \( \hat{i} = 0 \) if no such index exists.

5 return \( f_{\hat{i}+1} \cdots f_\ell e \)

Lemma 14. For any \( e \in B \) there is at most one \( f \in B \) such that \( f \prec e \).

Proof. Take a sibling \( e' \) of \( e \) and a closed path \( e'p \). Let \( f \) be the last branch on \( e'p \) (it exists since its first edge \( e' \) is a branch) and let \( fq \) be the suffix of \( e'p \) starting with \( f \), where \( q \) is univocal. Assume \( f \prec e \) and let \( fqe \) be an omnitig with \( q \) univocal. By Lemma 2, \( q \) is an open path, and by Lemma 5, \( fqe \) is a suffix of \( e'pe \), thus \( f = f \) and \( \hat{q} = q \). ▶

Our algorithm for computing the left-maximal omnitig ending with a given branch \( e \) works as follows. We first check whether the first case of Theorem 8 occurs, by verifying the condition provided therein. If not, then we consider the suffix \( fq \) of \( e'p \) defined as in the proof of Lemma 14. We have two cases.

1. If \( fq \) is not an omnitig. Then, an invocation of LongestSuffix(fqe) yields the only left-maximal omnitig ending with \( e \).

2. If \( fq \) is an omnitig. Then, \( s(f) \neq s(e) \) since \( f \) is open, thus \( f \prec e \). In this case, we apply the procedure recursively to the branch \( f \), obtaining an omnitig \( w'' \). Then, the left-maximal omnitig ending with \( e \) must be a suffix of \( w''qe \), and can be obtained as LongestSuffix(w''qe).

Lemma 15 is crucial in showing that the recursion is well-founded. As we will show later, thanks to memoization, this recursive application allows to reuse the computational effort and leads to a faster worst-case running time.

Lemma 15. The relation \( \prec \) is acyclic.

To achieve the claimed \( O(nm) \) running time, we need a further improvement. We recall the definition of strong bridge in a strongly connected graph [3].

Definition 16. An edge \( e \) is a strong bridge if, by removing \( e \), the graph is no longer strongly connected. Equivalently, there is a pair of nodes \( u, v \), such that every path from \( u \) to \( v \) contains \( e \).

The lemma below states that omnitigs containing non-strong-bridges have a simpler structure.

Lemma 17. If \( fq \) is an omnitig and an open path, and \( f \) is not a strong bridge, then \( q \) is univocal.

Proof. A minimal counterexample is an omnitig \( fqe \), where \( fqe \) is an open path and \( e \) is a branch. Fix a sibling \( e' \) of \( e \), and take a closed path \( e'p \) such that \( p \) does not contain \( f \), which exists since \( f \) is not a strong bridge. By Theorem 8, \( fqe \) is a suffix of \( p \): a contradiction since \( p \) does not contain \( f \). ▶
Algorithm 2: Computing the only left-maximal omnitig ending with a branch $e$.

1. **Function OmnitigEndingWith($e$)**
   
   **Input**: A branch $e$.
   
   **Returns**: The only left-maximal omnitig $we$.

2. Let $e'$ be any sibling of $e$ and $e'p$ be any closed path starting with $e'$.
3. Let $f$ be the last branch of $e'p$ (possibly $f = e'$) and $fq$ the suffix of $e'p$ starting with $f$.
4. Let $p'$ be the longest $R$-univocal path to $s(e)$.
5. if $e$ has only one sibling $e'$ and $p$ is univocal then return $p'e'pe$
6. if $e$ is not a strong bridge then return $p'e$
7. $w' \leftarrow$ LongestSuffix($fqe$)
8. if $w' \neq fq$ then return $w'$
9. $w'' \leftarrow$ OmnitigEndingWith($f$)
10. return LongestSuffix($w''qe$)  \(\triangleright\) OmnitigEndingWith is memoized

Algorithm 3: Computing all the maximal omnitigs.

1. $W \leftarrow \emptyset$
2. for $e \in B$ do
   
   3. $w \leftarrow$ OmnitigEndingWith($e$)
   4. Let $p$ be the longest univocal path from $t(e)$.
   5. $W \leftarrow W \cup \{wp\}$
3. end
4. Remove from $W$ the non-right-maximal walks.
5. return $W$

It is known that there are at most $2n - 2 = O(n)$ strong bridges in a given graph, and they can be computed in $O(m)$ time [3, 1]. The observation of Lemma 17 allows to handle those branches $e$ which are not strong bridges in a special way, and apply the full algorithm only on the $O(n)$ strong bridges. The procedure just described is illustrated in Algorithm 2.

**Lemma 18.** The function OmnitigEndingWith in Algorithm 2 is correct.

The full algorithm (Algorithm 3) amounts to computing, for each branch $e \in B$, the left-maximal omnitig ending with $e$, and then appending the longest possible univocal suffix.

**Theorem 19.** Algorithm 3 is correct and can be implemented to run in time $O(nm)$.

**Proof.** It is clear from Lemma 18 and Lemma 3 that Algorithm 3 terminates and returns a set $W$ containing only left-maximal omnitigs. For correctness, we only need to show that, after the for-loop, $W$ contains all the maximal omnitigs. Consider any maximal omnitig $w$. By Lemma 4, $w$ contains a branch. Let $e$ be the last branch of $w$, and write $w = w'e$ where $p$ is univocal. By Lemma 3, $w'e$ is left-maximal (otherwise also $w = w'ep$ is not left-maximal), and $p$ is the longest univocal path from $t(e)$, (otherwise $w = w'ep$ is not right-maximal). By Lemma 18, in the iteration of the for-loop, relative to the branch $e \in B$, the call OmnitigEndingWith($e$) returns $w'e$, and $w'ep$ is added to $W$.

To prove our bound on the running time, we observe that, when the function OmnitigEndingWith returns before line 7, then it takes $O(n)$ time only. Indeed, the length of
the open paths $p$ and $p'$ is $O(n)$. Moreover, when the condition at line 5 occurs, then the path $p$ is univocal, and its construction can be performed in $O(n)$ time, without running a full visit of the graph. These executions of OmnitigEndingWith account for an overall running time $O(nm)$, due to memoization, since there are $O(m)$ branches.

The execution continues after line 7 only $O(n)$ times, since the number of strong bridges is $O(n)$. In this case, the running time is dominated by the calls to LongestSuffix, which take $O(m)$ time each by Lemma 12. Again, due to memoization, the overall running time is $O(nm)$. The set of strong bridges is computed once at the beginning, in linear time.

It remains to show how to implement line 7 in time $O(nm)$. First, the total length of the walks in $W$ is $O(nm)$, because to each of the $O(m)$ walks returned by OmnitigEndingWith, each of length $O(n)$ (by Corollary 10), we append a path, thus having length $O(nm)$. One way to remove the non-right-maximal omnitigs from $W$ is to regard each walk in $W$ as a string over the alphabet $E$, construct a trie containing them, in time $O(nm)$, and remove those ending in an internal node.

Finally, we would like to remark on the Y-to-V reduction. Let $v$ be a node that has exactly one in-neighbor $u$ and more than one out-neighbors $w_1, \ldots, w_d$. The Y-to-V reduction applied to $v$ removes $v$ and its incident edges and adds an edge from $u$ to $w_i$, for all $1 \leq i \leq d$. The Y-to-V reduction was suggested as a pre-processing step to the omnitig algorithm in [17] to improve the running time. However, this reduction can destroy some omnitigs, see Figure 5.

5 Experimental results

We implemented Algorithm 3 using the code base of [17]. We focused our experiments on measuring the running time improvements, since the practical merits of omnitigs for genome assembly were discussed in [17]. The algorithms were run on a machine with Intel Xeon 2.10GHz CPUs. Because the Y-to-V transformation is not omnitig-preserving, we disabled it from the code of [17]. We circularized three reference sequences of human chromosomes 2, 10, and 14. Each had a length of 243, 136 and 107 million nucleotides, respectively. We built the edge-centric de Bruijn graph for each, using $k = 55$. This is a typical genome graph on which contig assembly is performed.

As shown in Table 1, our algorithm was 9–12 times faster on a single thread, suggesting that our theoretical improvements indeed translate into faster running times. For the largest dataset, our algorithm took just over 2 hours, while [17] took over 22 hours. We also observe, as expected, that the running time depends on the size of the graph and the number of omnitigs, and not on their length.

6 Conclusion

Apart from its application to genome assembly, the problem addressed in this paper is a fundamental graph theoretical one. It also fits into a line of research for finding all partial solutions common to natural notions of walks in graphs, such as Eulerian walks [18] or shortest edge-covering walks [12]. We presented here an optimal $O(nm)$ algorithm for finding all maximal omnitigs and showed that it can be an order of magnitude faster than a previous one based on exhaustive visits. When applied to genome assembly, our algorithm remains significantly slower than finding unitigs. However, we believe that an embarrassingly parallel implementation is possible, and that it will improve running time by another order of magnitude in practice.

Abstract

We show that it is possible to store a dynamic ordered set $S(n, u)$ of $n$ integers drawn from a bounded universe of size $u$ in space close to the information-theoretic lower bound and yet preserve the asymptotic time optimality of the operations. Our results leverage on the Elias-Fano representation of $S(n, u)$ which takes $EF(S(n, u)) = n\lceil \log \frac{u}{n} \rceil + 2n$ bits of space and can be shown to be less than half a bit per element away from the information-theoretic minimum.

Considering a RAM model with memory words of $\Theta(\log u)$ bits, we focus on the case in which the integers of $S$ are drawn from a polynomial universe of size $u = n^\gamma$, for any $\gamma = \Theta(1)$. We represent $S(n, u)$ with $EF(S(n, u)) + o(n)$ bits of space and: 1. support static predecessor/successor queries in $O(\min\{1 + \log \frac{u}{n}, \log \log n\})$; 2. make $S$ grow in an append-only fashion by spending $O(1)$ per inserted element; 3. support random access in $O(\log n/\log \log n)$ worst-case, insertions/deletions in $O(\log n/\log \log n)$ amortized and predecessor/successor queries in $O(\min\{1 + \log \frac{u}{n}, \log \log n\})$ worst-case time. These time bounds are optimal.

Keywords and phrases succinct data structures, integer sets, predecessor problem, Elias-Fano

Introduction

The problem we consider is the one of representing in compressed space a dynamic ordered set $S$ of $n$ integer keys, which is a fundamental textbook problem (see the introduction to parts III and V of [8]). In general, any self-balancing search tree data structure, e.g., AVL or Red-Black tree, solves the problem optimally in the comparison model, by implementing all operations in $O(\log n)$ worst-case time and using linear space [8]. However, by exploiting the fact that the stored keys are drawn integers from a bounded universe of size $u$, the problem is known to admit more efficient solutions in terms of asymptotic time complexity while still retaining linear space [8, 23, 26, 30, 13, 14]. Classical examples include the van Emde Boas tree [26, 27, 28], $x/y$-fast trie [30] and the fusion tree [14], that was the first data structure able to surpass the information-theoretic lower bound, by exhibiting an optimal [13] amount of time per operation within a number of memory words proportional to the size of the input. Some efforts have been spent in trying to reduce the space requirements of the representation [16, 18, 25] but known compressed solutions do not closely match the information-theoretic lower bound of the underlying integer set.

* This work was partially supported by the EU H2020 Program under the scheme INFRAIA-1-2014-2015: Research Infrastructures, grant agreement #654024 SoBigData: Social Mining & Big Data Ecosystem and by the Pegaso Project, POR FSE 2014-2020.
In this paper we show that it is possible to preserve the optimal bounds for the operations under almost optimal space requirements. The key ingredient of our data structures is the Elias-Fano representation of monotone integer sequences [10, 11]. In particular, Elias-Fano encodes a monotone integer sequence $S(n, u)$ in $\text{EF}(S(n, u)) = n\lceil \log u \rceil + 2n$ bits, which can be shown to be less than half a bit per element away from optimality [10], maintaining the capability of randomly access an integer in $O(1)$ worst-case time. The query Predecessor, which, given an integer $x$, returns $\max\{y \in S : y < x\}$, is possible as well over the compressed sequence in $O(1 + \log u)$ worst-case time. These properties make Elias-Fano extremely efficient on crucial practical applications, e.g., inverted indexes compression, just to mention the most noticeable one. Since inverted indexes can indeed be regarded as being a collection of sorted integer sequences, recent works [29, 20] have shown that Elias-Fano exhibits the best time/space trade-off thanks to its efficient search capabilities and strong theoretical guarantees.

The natural question is whether it is possible to extend the static Elias-Fano representation to dynamic scenarios, in which integers can also be inserted/deleted in/from $S$. To this end, we consider the case in which the $n$ integers of $S$ are drawn from a polynomial universe of size $u = n^\gamma$, for any $\gamma = \Theta(1)$. This is the classical operational setting as considered by Fredman and Saks [13] (list representation problem) and let us concentrate on the typical case of practical interest. In order to characterize the asymptotic complexity of the data structures described in the paper and review the literature, we use a RAM model with word size $w = \Theta(\log u)$ bits. We also adopt the usual trans-dichotomous assumption [14], making $w$ grow with $n$ as needed. We maintain $S(n, u)$ using $\text{EF}(S(n, u)) + o(n)$ bits of space, hence introducing a sublinear space overhead with respect to its static Elias-Fano representation, and show how:

1. static predecessor/successor queries can be supported in $O(\min\{1 + \log u, \log \log n\})$ worst-case time (note that the first term of the bound, i.e., $O(1 + \log u)$, is optimal only for polynomial universes of size $u = n^\gamma$ with $1 \leq \gamma \leq 1 + \log \log n / \log n$);
2. to extend $S$ in an append-only fashion, i.e., by assuming that integers are inserted in the data structure in sorted order, using a constant amount of work per integer;
3. to maintain $S$ in a fully dynamic way, supporting random access in $O(\log n / \log \log n)$ worst-case, insertions/deletions in $O(\log n / \log \log n)$ amortized and predecessor/successor queries in $O(\min\{1 + \log u, \log \log n\})$ worst-case time.

2 Related Work

We organize the discussion of the related work in three parts. The first part concerns the review of the results about the static predecessor problem. The second one explains in details the (static) Elias-Fano representation of monotone integer sequences because it forms the backbone of our solutions. The last part finally describes the results closest to our work for the maintenance of a dynamic integer set.

2.1 Static Predecessor Problem

We could solve the static predecessor problem in $O(1)$ worst-case by storing all results to every possible query using perfect hashing [12] in $O(u)$ words of space. In order to not
trivialize the problem, assume we have a polynomial space budget, e.g., we deal with a data structure occupying \( O(n^{O(1)}) \) words.

Ajtai [1] proved the first \( \omega(1) \) lower bound, claiming that \( \forall w, \exists n \text{ that gives } \Omega(\sqrt{\log w}) \) query time. Only ten years later Beame and Fich [3, 4] proved two strong bounds for any cell-probe data structure\(^1\). They proved that \( \forall w, \exists n \text{ that gives } \Omega(\log w / \log \log w) \) query time and that \( \forall n, \exists w \text{ that gives } \Omega(\sqrt{\log n} / \log \log n) \) query time. They also gave a static data structure achieving \( O(\min\{\log w / \log \log w, \sqrt{\log n} / \log \log n\}) \) which is, therefore, optimal. Building on a long line of research, Pătraşcu and Thorup [21, 22] finally proved the following optimal space-time trade-off for a static data structure taking \( m = n2^w \) bits of space, with \( a = \log \frac{m}{n} - \log w \)

\[
\Theta\left(\min\left\{ \log_{w} n, \log\frac{w \log n}{a}, \log\left(\frac{w}{\log n} \log\frac{w}{a}\right), \log\left(\log\frac{w}{n} / \log\log\frac{n}{a}\right)\right\}\right).
\]

This lower bound holds for cell-probe, RAM, trans-dichotomous RAM, external memory and communication game models. The first branch of the trade-off indicates that, whenever we are in RAM or external memory with one integer fitting in one memory word, fusion trees are optimal, as these require \( O(\log_{w} n) = O(\log n / \log w) \) query time. The second branch holds for polynomial universes, i.e., whenever \( u = n^\gamma \), for any \( \gamma = \Theta(1) \). In such case we have that \( w = \Theta(\log u) = \gamma \log n \), therefore \( y \)-fast tries [30] and van Emde Boas trees [26, 27, 28] are optimal with query time \( O(\log \log u) = O(\log \log n) \). Finally, the last two branches of the trade-off treat the case for super-polynomial universes. In particular, the third branch matches the lower bound by Beame and Fich [3, 4] that requires \( n^{O(1)} \) words of space; the fourth branch improves this space occupancy, showing that \( n^{1+1/\exp(\log^{1-\epsilon} \log u)} \) words are sufficient, for any \( \epsilon > 0 \).

### 2.2 Static Elias-Fano Representation

The integer encoding we describe in this section was independently proposed by Peter Elias [10] and Robert Mario Fano [11], hence its name. Given a monotonically increasing sequence \( S(n, u) \) of \( n \) positive integers drawn from a universe of size \( u \) (i.e., \( S[i-1] \leq S[i] \), for any \( 1 \leq i < n \), with \( S[n-1] \leq u \)), we write each \( S[i] \) in binary using \( \lfloor \log u \rfloor \) bits. Each binary representation is then split into two parts: a high part consisting in the first \( \lceil \log n \rceil \) most significant bits that we call high bits and a low part consisting in the remaining \( \ell = \lfloor \log \frac{n}{u} \rfloor \) bits that we similarly call low bits. Let us call \( h_i \) and \( \ell_i \) the values of high and low bits of \( S[i] \) respectively. The Elias-Fano representation of \( S \) is given by the encoding of the high and low parts. The array \( L = [\ell_0, \ldots, \ell_{n-1}] \) is stored in fixed-width and represents the encoding of the low parts. Concerning the high bits, we represent them in negated unary\(^2\) using a bit vector of \( n + \lceil \frac{n}{u} \rceil \leq 2n \) bits as follows. We start from a 0-valued bit vector \( H \) and set the bit in position \( h_i + i \), for all \( i \in [0, n] \). The effect is that now the \( k \)-th unary integer \( m \) of \( H \) indicates that \( m \) integers of \( S \) have high bits equal to \( k \). Finally the Elias-Fano representation of \( S \) is given by the concatenation of \( H \) and \( L \) and overall takes

\[
\text{EF}(S(n, u)) = n \left\lfloor \log \frac{u}{n} \right\rfloor + 2n \text{ bits.}
\]

---

\(^1\) In the cell-probe computational model, described by Yao [31], computation is for free given that we only take into account word reads. It is not a very realistic model of computation, but it is useful to prove lower bounds because it is a stronger model than RAM and trans-dichotomous RAM.

\(^2\) The negated unary representation of an integer \( x \), is the bitwise NOT of its unary representation \( U(x) \). An example: \( U(5) = 00001 \) and \( \text{NOT}(U(5)) = 11110 \).
While we can opt for an arbitrary split ranging from 0 to $\lfloor \log u \rfloor$ into high and low parts, it can be shown that the value $\ell = \lfloor \log \frac{u}{n} \rfloor$ minimizes the overall space occupancy of the encoding [10]. As the information theoretic lower bound for a monotone sequence of $n$ elements drawn from a universe of size $u$ is $\lceil \log \left( \frac{u+n}{n} \right) \rceil \approx n \log \frac{u+n}{n} + n \log e$ bits, it can be shown that less than half a bit is wasted per element by the space bound in (2) [10]. Since we set a bit for every $i \in [0, n)$ in $H$ and each $h_i$ is extracted in $O(1)$ time from $S[i]$, it follows that $S$ gets encoded with Elias-Fano in $\Theta(n)$ time.

Despite the simplicity of the encoding, it is possible to randomly access an integer from a sequence encoded with Elias-Fano without decompressing it. We refer to this operation as $\text{Access}(i)$ in the following, which returns the $i$-th (smallest) element of the sequence. The operation is supported using an auxiliary data structure that is built on bit vector $H$, able to efficiently answer $\text{Select}_1(i)$ queries, that return the position in $H$ of the $i$-th 1 bit. This auxiliary data structure is succinct in the sense that it is negligibly small compared to $\text{EF}(S(n, u))$, requiring only $o(n)$ additional bits [7, 29].

Using the $\text{Select}_1$ primitive, it is possible to implement $\text{Access}(i)$, which returns $S[i]$ for any $i \in [0, n)$, in $O(1)$. We basically have to re-link together the high and low bits of an integer, previously split up during the encoding phase. The high bits $\ell_i$ are trivial to retrieve as we need to read the range of bits $[i\ell, (i+1)\ell)$ from $L$. Note that we also need to store the quantity $\ell$: a global redundancy of $O(\log u)$ bits is sufficient. The retrieval of the high bits deserve, instead, a bit more care. Since we write in negated unary how many integers share the same high part, we have a bit set for every integer of $S$ and a zero for every distinct high part. Therefore, to retrieve the high bits of the $i$-th integer, we need to know how many zeros are present in $H[0, \text{Select}_1(i))$. This quantity is evaluated on $H$ in $O(1)$ as $\text{Rank}_0(\text{Select}_1(i)) = \text{Select}_1(i) - i$. Notice, therefore, that the succinct rank/select data structure does not have to support $\text{Rank}$. Finally, linking the high and low bits is as simple as: $\text{Access}(i) = ((\text{Select}_1(i) - i) \ll \ell_i) \lor \ell_i$, where $\ll$ is the left shift operator and $\lor$ is the bitwise OR.

The query $\text{Successor}(x)$ is supported in $O(1 + \log \frac{u}{n})$ time, as follows. Let $h_x$ be the high bits of $x$, i.e., its first $\lceil \log n \rceil$ most significant bits. Then $p_1 = \text{Select}_0(h_x) - h_x$ represents the number of integers in $S$ whose high bits are less than $h_x$. On the other hand, $p_2 = \text{Select}_0(h_x + 1) - h_x - 1$ gives us the position at which the elements having high bits greater than $h_x$ start. These two preliminary operations take $O(1)$. We can now determine the successor of $x$ by binary searching in this interval which may contain up to $u/n$ integers. The algorithm for $\text{Predecessor}(x)$ runs in a similar way. In particular, it could be that $\text{Predecessor}(x)$ lies before the interval $[p_1, p_2)$: in this case $S[p_1 - 1]$ is the element to return.

### 2.3 Dynamic Problems

We now review the most important results concerning the maintenance of a dynamic set of integers/binary strings, following the chronological order of their proposal.

The van Emde Boas tree is a recursive data structure that maintains $S$ in $O(u)$ words of space and supports the operations: $\text{Search}$ which tests whether a given integer is present or not in $S$, $\text{Insert}/\text{Delete}$ and $\text{Predecessor}/\text{Successor}$ all in $O(\log w)$ worst-case time [26, 27, 28]. Willard [30] improved the space bound to $O(n)$ words by introducing the $y$-fast trie that supports $\text{Search}$ and $\text{Predecessor}/\text{Successor}$ queries in $O(\log w)$ worst-case time, $\text{Insert}/\text{Delete}$ in amortized $O(\log w)$ time.

---

3 We report the bound as $O(1 + \log \frac{u}{n})$, instead of $O(\log \frac{n}{u})$, to cope with the case $n = u$. 
The work by Fredman and Saks [13] is useful to understand which lower bounds apply to the problem we consider in the paper. They described the list representation problem, i.e., how to maintain \( S \) under the triad of operations \( \text{Access/Insert/Delete} \), and proved that it can be solved in \( \Omega(\log n / \log \log n) \) amortized time per operation if \( w \leq \log^\gamma n \) for some \( \gamma \). No space bound is posed on such problem. Their lower bound does not apply to dynamic predecessor queries and holds for the cell-probe computational model [31]. Extending the result to the dynamic predecessor problem, they proved that any cell-probe data structure representing \( S \) using \( (\log n)^{(1)} \) bits per memory cell and \( n^{(1)} \) worst-case time for insertions, requires \( \Omega(\sqrt{\log n} / \log \log n) \) worst-case query time. They also proved that on a RAM, the dynamic predecessor problem can be solved in \( \mathcal{O}(\min\{\log \log n \cdot \log w / \log \log w, \sqrt{\log n / \log \log n}\}) \), using \( \mathcal{O}(n) \) words. This bound was matched by Andersson and Thorup [2] with the so-called exponential search tree. This data structure has an optimal bound of \( \mathcal{O}(\sqrt{\log n} / \log \log n) \) worst-case time for searching and updating \( S \), using polynomial space. Raman, Raman and Rao [24] also addressed the list representation problem\(^4\) for arrays of length \( n \) by providing two solutions. Their first data structure supports \( \text{Access} \) in \( \mathcal{O}(1) \) and \( \text{Insert/} \text{Delete} \) in \( \mathcal{O}(n^\epsilon) \) worst-case time for any fixed positive \( \epsilon < 1 \); the second data structure implements all the three operations in \( \mathcal{O}(\log n / \log \log n) \) amortized time. Both data structures use \( o(n) \) bits of redundancy and the time bounds are optimal.

Fredman and Willard [14] showed that dynamic predecessor queries can be answered in \( \mathcal{O}(\log n / \log \log n) \) time by using the fusion tree. This data structure is a \( B \)-tree with branching factor \( B = \Theta(\log n) \) that stores in each internal node a fusion node, a small data structure able of answering predecessor queries in \( \mathcal{O}(1) \) for sets up to \( w^{1/3} \) integers. Updating a fusion node takes, however, \( \mathcal{O}(B^2) \) time. The overall space of the data structure is \( \mathcal{O}(n) \) words. The work by Pătraşcu and Thorup [23] has recently shown that it is possible to “dynamize” the fusion node, by supporting \( \text{Insert} \) and \( \text{Delete} \) in \( \mathcal{O}(1) \). As a result, they have proposed a data structure representing \( S \) in \( \mathcal{O}(n) \) words and optimal \( \mathcal{O}(\log n / \log w) \) running time for the operations \( \text{Insert, Delete, Predecessor, Successor, Rank and Select.} \)

We also mention a few additional results, that will be useful in the following. Bille et al. [5] recently combined the static solution of Demaine and Pătraşcu [9] with the one by Pătraşcu and Thorup [23] to support dynamic prefix sums over an array of size \( n \) in optimal \( \mathcal{O}(\log n / \log(w/\delta)) \) time per operation and linear space, where \( \delta \) is the number of bits needed to encode the quantity that we sum to the elements of the array. Though not devised for integer sets, the extended CRAM (Compressed Random Access Memory) data structure described by Jansson, Sadakane and Sung [17] allows a string \( S \) of length \( n \) to be stored using its \( k \)-th order empirical entropy \( nH_k(S) \) plus a redundancy of \( \mathcal{O}(n \log \sigma (k \log \sigma + (k + 1) \log \log n) / \log n) \) bits for every \( 0 \leq k < \log_\sigma n \), where \( \sigma \) is the size of the alphabet, in such a way that \( \text{Insert/} \text{Delete} \) of characters and \( \text{Access} \) to any consecutive \( \log_\sigma n \) bits are all supported in optimal \( \mathcal{O}(\log n / \log \log n) \) worst-case time. We will exploit the part of this work dedicated to the memory management. Grossi et al. [15] improved the previous space bound by using \( nH_k(S) + \mathcal{O}(n \log \log n / \log_\sigma n) \) bits and maintaining the asymptotic optimality for all operations. The paper by Navarro and Nekrich [19] illustrates a data structure supporting \( \text{Access, Rank/Select} \) queries, as well as symbol insertions/deletions on \( S \) in optimal \( \mathcal{O}(\log n / \log \log n) \) time and taking \( nH_0(S) + \mathcal{O}(n + \sigma (\log \sigma + \log^{1+\epsilon} n)) \) bits of space. Of particular interest for our purposes, is the data structure described in Appendix A.1 concerning the organization of data in small blocks. The high-level idea is to maintain a

\(^4\) In their paper [24], the authors refer to the list representation problem, as introduced by Fredman and Saks [13], as the dynamic array problem. Also, the operation \( \text{Access} \) is named \( \text{Index}. \)
30:6 Dynamic Elias-Fano Representation

We can solve basic search operations in $O(1)$ time by using a small pre-computed table. In Section 5 we will make use of a similar data structure, in order to handle mini blocks of sorted integers, which avoids the use of pre-computed tables.

3 Static Predecessor Queries in Optimal Time

In this section we are interested in determining the optimal running time of $\text{Predecessor}$ for the Elias-Fano space bound in (2). As mentioned in Section 1, our focus is on polynomial universes, i.e., $u = n^\gamma$ for any $\gamma = \Theta(1)$, for which the second branch of the time/space trade-off in (1) becomes optimal. The following theorem shows that adding $o(n)$ bits of redundancy to $\text{EF}(S(n, u))$ is enough to support $\text{Predecessor}$ queries in optimal time.

$\textbf{Theorem 1.}$ There exists a data structure representing an ordered set $S(n, u)$ of $n$ integers drawn from a polynomial universe of size $u = n^\gamma$, for any $\gamma = \Theta(1)$, that takes $\text{EF}(S(n, u)) + o(n)$ bits of space and supports $\text{Access}$ in $O(1)$ worst-case and $\text{Predecessor}/\text{Successor}$ queries in optimal $O(\min\{1 + \log \frac{n}{u}, \log \log n\})$ worst-case time.

We resort on the time/space trade-off (1) by Pătrașcu and Thorup [21, 22]. In our case, $a = \log([\log\frac{n}{u}] + 2)$ and $w = \Theta(\log u) = \gamma \log n$. In such setting, the second term of the trade-off becomes $\log \frac{\gamma - 1}{u} \log n / \log([\log\frac{n}{u}] + 2) = O(\log \log n)$. This proves that $y$-fast tries and van Emde Boas trees are optimal for static $\text{Predecessor}$ queries within the Elias-Fano space bound. However, such bound only depends on $n$, whereas the plain Elias-Fano bound for $\text{Predecessor}$ of $O(1 + \log \frac{n}{u})$, introduced in Subsection 2.2, depends on both $n$ and $u$. On the other hand, the relation $u = n^\gamma$ relates the two parameter by means of the constant $\gamma = \Theta(1)$. It is clear that varying $\gamma$ one of the two bounds becomes optimal. Indeed, comparing $1 + \log \frac{n}{u}$ with $\log \log n$, we have that $1 + \log \frac{n}{u} \leq \log \log n$ whenever $u \leq \frac{2}{\gamma} \log n$, i.e., when $n^{\gamma-1} \leq \frac{1}{\gamma} \log n$. From this last condition we derive that the plain Elias-Fano is faster than van Emde Boas whenever $1 \leq \gamma \leq 1 + \frac{\log \log n}{\log \log n}$. In this case the static Elias-Fano representation does not need to be augmented. When, instead, $\gamma > 1 + \frac{\log \log n}{\log \log n}$, the query time $O(\log \log n)$ is optimal and exponentially better than plain Elias-Fano. Therefore, $O(\min\{1 + \log \frac{n}{u}, \log \log n\})$ is an accurate characterization of the $\text{Predecessor}$ time bound.

We are left to describe a data structure matching the bound of $O(\log \log n)$, within $o(n)$ bits of additional space. We divide $S$ into $\lceil n/\log^2 u \rceil$ blocks of $\log^2 u$ integers each (the last block may contain less integers). We can solve $\text{Predecessor}$ queries in a block in $O(\log \log u) = O(\log \log n)$ time by applying binary search. Now, we need a data structure on top of $S$ that allows us to identify the proper block in $O(\log \log n)$ time. Call the first element of a block its lower bound. We attach to $S$ a $y$-fast trie storing the lower bounds of the blocks. More precisely, each leaf in the $y$-fast trie holds the lower bound of a block and its position in $S$. The integers stored in the $y$-fast trie are $\lceil n/\log^2 u \rceil$, therefore its space is $O(n/\log^2 u) = o(n)$ bits. To identify the block where the predecessor of $x$ lies in, we answer a partial $\text{Predecessor}(x)$ query among the integers stored in the $y$-fast trie in $O(\log \log n)$ worst-case time. The position $p$ in $S$ of the block’s lower bound, associated to the identified partial answer, indicates that the search must continue in the block $S[p, \min\{p + \log^2 u, n\}]$.

Concluding this section, observe that the time bound for $\text{Predecessor}$ queries is always at most $O(\log \log n)$ except when $1 \leq \gamma \leq 1 + \frac{\log \log n}{\log \log n}$; in this case, the plain Elias-Fano
representation beats the time bound of $O(\log \log n)$. Therefore, in what follows we report the bound as $O(\min\{1 + \log \frac{\gamma}{n}, \log \log n\})$ but discuss the case for $\gamma > 1 + \frac{\log \log n}{\log m}$.

4 Extensible Elias-Fano Representation

When the integers are inserted in sorted order, we obtain an efficient extensible representation as these can only be added at the end of the sequence by means of an Append operation. This is a scenario of practical interest as it is the operational setting of append-only inverted indexes, e.g., the one of Twitter [6].

\textbf{Theorem 2.} There exists a data structure representing an ordered set $S(n, u)$ of $n$ integers, drawn from a polynomial universe of size $u = n^\gamma$, for any $\gamma = \Theta(1)$, that takes $EF(S(n, u)) + o(n)$ bits of space and supports: Append in $O(1)$ amortized, Access in $O(1)$ worst-case and Predecessor/Successor queries in optimal $O(\min\{1 + \log \frac{\gamma}{n}, \log \log n\})$ worst-case time.

We maintain an array $B$ of size $m$ in which integers are appended uncompressed. This array acts as a buffer, which is periodically encoded with Elias-Fano in $\Theta(m)$ time and dumped, so that new integers can be successfully appended. Each compressed representation of the buffer is appended in an array of blocks encoded with Elias-Fano. More precisely, when $B$ becomes full we encode with Elias-Fano its corresponding differential buffer, i.e., the buffer whose values are $B[i] - B[0]$, $0 \leq i < m$. Each time the buffer is compressed, we append in another array $C$ the pair $(\text{base, low_bits}) = (B[0], \lfloor \log(B[m-1]/m) \rfloor)$, i.e., the buffer lower bound value and the number of bits needed to encode the average gap of the Elias-Fano representation of the buffer.

Apart from the space taken by the compressed blocks, the space of the data structure is given by the following contributions:

- $(m+1)\log u$ bits for the buffer $B$ of uncompressed integers and its size;
- $O(\lceil \frac{u}{m} \rceil \log n)$ bits for pointers to rank/select data structures, low and high bit arrays;
- $O(\lceil \frac{u}{m} \rceil \log u)$ bits for the array $C$.

Summing up, the redundancy is $O((m+1 + \lceil \frac{n}{m} \rceil)\log u)$ bits. We use a buffer of size $m = \log^2 u$ and, as done in Section 3, we index the buffer lower bounds in a $y$-fast trie. More precisely, each leaf of the fast trie stores a buffer lower bound and the index of the compressed block to which the lower bound belongs to. The values stored in the $y$-fast trie are $\lceil n/\log^2 u \rceil$, thus requiring $o(n)$ bits of space. The redundancy $O((m+1 + \lceil \frac{n}{m} \rceil)\log u)$ becomes $o(n)$ bits for $n = \omega(\log^2 u)$, which is already satisfied by requiring that $\gamma = \Theta(1)$.

To take into account the space taken by the representation of the blocks, we use the property that splitting a block encoded with Elias-Fano into two sub-blocks never increases the cost of representation of the block. This is possible because each sub-block can be encoded with a universe relative to the sub-block, which is smaller than the original block universe, by subtracting to each integer the lower bound of the sub-block. The following property can be easily extended to work with an arbitrary number of splits.

\textbf{Property 1.} Consider a monotone sequence $S$ of $n$ integers. Let $S[i, j]$ indicate the range of $S$ delimited by endpoints $i$ and $j$. Then for any $i$, $k$ and $j$ such that $0 \leq i < k < j < n$, we have $EF(S[i, k]) + EF(S[k, j]) \leq EF(S[i, j])$.

\textbf{Proof.} Let $m$ and $u$ be respectively size and universe of the sub-sequence $S[i, j]$, and, similarly, let $m_1, m_2, u_1, u_2$ be the sizes and universes of the two sub-sequences $S[i, k]$ and $S[k, j]$ respectively. We have that $m = m_1 + m_2$ and $u = u_1 + u_2$. From Subsection 2.2, we know that $EF(S[i, j])$ takes $m\phi + m + \lceil \frac{m}{2u} \rceil$. Similarly $EF(S[i, k]) = m_1\phi_1 + m_1 + \lceil \frac{m_1}{2u_1} \rceil$ and $EF(S[k, j]) = m_2\phi_2 + m_2 + \lceil \frac{m_2}{2u_2} \rceil$. We have that $m\phi + m + \lceil \frac{m}{2u} \rceil = (m_1\phi_1 + m_1 + \lceil \frac{m_1}{2u_1} \rceil) + (m_2\phi_2 + m_2 + \lceil \frac{m_2}{2u_2} \rceil)$. Therefore, $EF(S[i, k]) + EF(S[k, j]) \leq EF(S[i, j])$. \hfill $\Box$
and $\text{EF}(S[k,j]) = m_2\phi_2 + m_2 + \lceil \frac{m\phi + m}{m_2} \rceil$. $\text{EF}(S[i,k])$ and $\text{EF}(S[k,j])$ are minimized by setting $\phi_1 = \lfloor \log \frac{n_1}{m_1} \rfloor$ and $\phi_2 = \lfloor \log \frac{n_2}{m_2} \rfloor$ respectively [10], therefore, by replacing $\phi_1$ and $\phi_2$ with $\phi$, we have that $\text{EF}(S[i,k]) + \text{EF}(S[k,j]) \leq m_1\phi + m_2\phi + m_1 + m_2 + \lceil \frac{m\phi}{m_2} \rceil + \lceil \frac{m\phi}{m_1} \rceil = \text{EF}(S[i,j])$.

The operations are supported as follows. Since we compress the buffer each time it fills up (by taking $\Theta(m)$ time), $\text{Append}$ is performed in $\mathcal{O}(1)$ amortized time. Appending new integers in the buffer accumulates a credit of $\mathcal{O}(\log^2 u)$ which largely pays the amortized cost $\mathcal{O}(\log \log u)$ of inserting a buffer lower bound into the $y$-fast trie. To $\text{Access}$ the $i$-th integer, we retrieve the element $x$ in position $i - jm$ from the compressed block of index $j = \lfloor \frac{i}{m} \rfloor$. This is done in $\mathcal{O}(1)$ worst-case time, since we know how many low bits are required to perform the access by reading $C[j].\text{low\_bits}$. We finally return the integer $x + C[j].\text{base}$. Predecessor queries are supported similarly as in the description of Theorem 1. Given the integer $x$, we first resolve a partial $\text{Predecessor}(x)$ query in the $y$-fast trie to identify the index $j$ of the compressed block in which the predecessor is located. Then we return $C[j].\text{base} + \text{Predecessor}(x - C[j].\text{base})$ by binary searching the block of index $j$ in $\mathcal{O}(\log \log u) = \mathcal{O}(\log \log n)$ worst-case time.

From Theorem 2, the following corollary easily follows.

- **Corollary 3.** There exists a data structure representing an ordered set $S(n,u)$ of $n = \omega(\log^2 u)$ integers drawn from a universe of size $u$ that takes $\text{EF}(S(n,u)) + o(n)$ bits of space and supports $\text{Append}$ and $\text{Access}$ operations in $\mathcal{O}(1)$ worst-case time.

Without using the $y$-fast trie we are able to achieve a worst-case running time for the $\text{Append}$ operation in Corollary 3 by using a classical de-amortization argument (note, however, that $\text{Predecessor}$ queries are not supported in optimal time anymore). We maintain two buffers, $B_1$ and $B_2$, instead of one. When one is full we use the other to store the elements that must be appended. Suppose $B_1$ is full. For each of the successive $m$ $\text{Append}$ operations, we compress one element from $B_1$ and append the new integer in $B_2$. These two steps require $\mathcal{O}(1)$ worst-case time each.

## 5 Dynamic Elias-Fano Representation

In this section we describe how the static Elias-Fano representation can be turned into an efficient dynamic data structure, i.e., supporting $\text{Access}$, $\text{Insert}$, $\text{Delete}$, $\text{Minimum}$, $\text{Maximum}$, $\text{Predecessor}$ and $\text{Successor}$ in optimal time and taking $\text{EF}(S(n,u)) + o(n)$ bits of space.

As already discussed in Subsection 2.3, Fredman and Saks [13] proved that $\mathcal{O}(\frac{\log n}{\log \log n})$ amortized time is optimal for any data structure maintaining a set of integers subject to $\text{Access}$, $\text{Insert}$ and $\text{Delete}$ (list representation problem). Their result holds when $w \leq \log^\gamma n$ for some $\gamma$, which covers the case of polynomial universes $u = n^\gamma$ since $\gamma \leq \log \gamma^{-1} n$, for any $\gamma \geq 1$ and $n \geq 2$. We operate, therefore, in the same setting as Theorems 1 and 2, considering integers drawn from a polynomial universe of size $u = n^\gamma$, for any $\gamma = \Theta(1)$. In this setting, Pătraşcu and Thorup [21] showed that $\mathcal{O}(\log \log n)$ query time of $y$-fast tries and van Emde Boas trees is optimal for the dynamic predecessor problem too.

- **Theorem 4.** There exists a data structure representing an ordered set $S(n,u)$ of $n$ integers drawn from a polynomial universe of size $u = n^\gamma$, for any $\gamma = \Theta(1)$, that takes $\text{EF}(S(n,u)) + o(n)$ bits of space and supports: $\text{Access}$ in $\mathcal{O}(\log n / \log \log n)$ worst-case; $\text{Insert/Dele} in \mathcal{O}(\log n / \log \log n)$ amortized; $\text{Minimum/Maximum}$ in $\mathcal{O}(1)$ and $\text{Predecessor/Successor}$ queries in $\mathcal{O}(\min\{1 + \log \frac{n}{n}, \log \log n\})$ worst-case time. These time bounds are optimal.
In what follows, we first describe the layout of the data structure and then analyze its space and time complexities.

5.1 Data Structure Description

We begin our description by showing how to handle a dynamic collection of mini blocks in succinct space, which is a key tool to obtain the full dynamic data structure. This result builds on an idea from [19], Appendix A.1.

5.1.1 Maintaining a Sorted Collection of Mini Blocks

Let $\mathcal{C}$ be a collection of $k = \mathcal{O}(\text{polylog } n)$ blocks of sorted integers, with the following properties. The blocks of $\mathcal{C}$ form a total order, i.e., $u_j \leq f_{j+1}$, for all $j = 1, \ldots , k-1$, where $f_j$ and $u_j$ indicate, respectively, the first and last element of the $j$-th block in the total order. Each block supports random access to its elements in constant time and is of size $\Theta(b) = \rho b$ with $\frac{1}{2} \leq \rho \leq 2$ and $b = \mathcal{O}(\text{polylog } n)$.

Lemma 5. The total order of the blocks of $\mathcal{C}$ can be maintained by using a data structure that takes $\mathcal{O}(\text{polylog } n \cdot \log \log n)$ bits of space and supports the following operations in $\mathcal{O}(\log \log n)$ worst-case time: Search($x$) which returns a pointer to the block containing the integer $x$; Access($i$) which returns the $i$-th integer of the total order; Insert/Delete of a block.

Pointers of $\mathcal{O}(\log \log n)$ bits to blocks are stored in the leaves of a $\tau$-ary tree $\mathcal{T}$, with $\tau = \Theta(\log^\sigma n)$ for some $0 < \sigma < 1$. Given that we have $\mathcal{O}(\text{polylog } n)$ leaves, the height of $\mathcal{T}$ is constant and equal to $\mathcal{O}(1/\sigma)$. $\mathcal{T}$ operates as a $B$-tree, in which internal nodes have $\Theta(\tau) = \rho \tau$ children.

Logically, we divide the information stored at each internal node into two levels of representation. For each of the two levels we store $\Theta(\tau)$ pairs, where the $i$-th pair maintains information about the sub-tree rooted in the $i$-th child. The pairs are stored following the order of the upper bounds of the blocks indexed in the sub-trees rooted in the node’s children. In the lower level, each pair contains a pointer to the sub-tree rooted in the child and the size of such sub-tree. The $\Theta(\tau)$ children sizes are kept in prefix sums to enable binary search. In the upper level, each pair contains a pointer to the right-most block indexed in the sub-tree rooted in its child and the size of such sub-tree. Each leaf holds, of course, only the lower level of information. Each node uses $\mathcal{O}(\tau(\log \log n + \log \log \log n)) = \mathcal{O}(\tau \log \log n) = \omega(\log n)$ bits, thus fitting in (less than) a machine word. The space taken by whole data structure is, therefore, $\mathcal{O}(\tau^{\mathcal{O}(1/\sigma)} \log \log n) = \mathcal{O}(\text{polylog } n \cdot \log \log n)$ bits.

We now detail how the operations are implemented. To support Search($x$), i.e., determining the block where the integer $x$ is comprised, we percolate $\mathcal{T}$, locating the correct child at each node in $\mathcal{O}(\log \tau) = \mathcal{O}(\log \log n)$ by binary searching on blocks’ upper bounds. Specifically, if the upper bounds of the $i$-th block is needed for comparison for some $1 \leq i \leq \Theta(\tau)$, we access the block following the pointer (to the right-most block) of the $i$-th pair stored in the upper level of the node and we retrieve the upper bound in $\mathcal{O}(1)$, given that we also know the size of the block. When we have to insert/delete an integer, we identify the proper block of the total order in/from which the integer must be inserted/deleted in $\mathcal{O}(\log \log n)$ time (as described for the Search operation) and update the pairs along the path from the root in constant time, as these pairs fits in $o(\log n)$ bits overall. If a split or merge of a block happens, it is handled as usual and solved in a constant number of $\mathcal{O}(1)$-time operations. During an Access($i$) query, we follow the proper root-to-leaf path in $\mathcal{T}$. The traversal of the data structure does not need to access the blocks directly, but instead uses their sizes to
determine the correct child at each level. By binary searching the sizes, we traverse the data structure in \(O(\log \log n)\) time. During the traversal of the path we also compute the sum \(\Delta\) of the sizes of the preceding blocks by summing to the current value of \(\Delta\), at each level, the value stored in the \((j-1)\)-th pair of the lower level if the \(j\)-th child is traversed. Finally we retrieve the \((i-\Delta)\)-th integer from the identified block in \(O(1)\), as the blocks of \(C\) support random access.

### 5.1.2 Full Data Structure Layout

Let \(\ell\) be \(\log n / \log \log n\) for the rest of the paper. We logically divide the sorted sequence \(S(n,u)\) into mini blocks of \(\Theta(\ell) = \rho \ell\) integers each. We organize the dynamic layout into two levels.

**Lower level.** We group \(O(\log^2 n)\) consecutive mini blocks together and index such collection using the data structure \(T\) described in Lemma 5. We refer to this collection as a “block” and say that \(T\) stores a block of \(O(\log^2 n)\) mini blocks. The set \(\{T_j\}_{j=1}^{k'}\), with \(k' = n/O(\ell \log^2 n)\), of all such data structures forms the lower level of the dynamic layout. Each \(T_j\) also stores the lower bound \(f_j\) of its block and the number of low bits required by its Elias-Fano representation in \(\Theta(\log u)\) bits, so that we can subtract \(f_j\) to all the integers belonging to the mini blocks of \(T_j\).

**Upper level.** The set \(\{f_j\}_{j=1}^{k'}\) of all the lower bounds of the blocks are indexed using an \(y\)-fast trie. The sizes of the blocks are maintained, instead, using the dynamic prefix sums data structure described in [5], which is a B-tree in which each node stores a dynamic prefix sums data structure operating on a small set of integers in \(O(1)\) time. In particular we use the operation \(\text{Update}(i, \Delta)\) of \(P\) as implemented in [5], which sums to the \(i\)-th integer of the data structure the quantity \(\Delta\) (that fits in \(\delta\) bits) and runs in optimal \(O(\log n / \log(w/\delta))\) worst-case time. In our setting this operation is supported in \(O(\ell)\) given that \(\delta = \Delta = 1\).

These two data structures, respectively named \(Y\) and \(P\) in the following, form the upper level of the dynamic layout. The \(j\)-th leaf of \(Y\) and \(P\) stores a \(O(\log n)\)-bit pointer to the data structure \(T_j\) in the lower level.

To handle the memory allocation for the mini blocks, we employ a different technique to manage the high and low part of their Elias-Fano representation. Recall from Subsection 2.2 that, given a sequence \(S(n,u)\), the high part of \(\text{EF}(S(n,u))\) consists in a bitvector of at most \(2n\) bits, whereas the low part is given by a vector of \(n \left\lceil \log u \right\rceil\)-bit integers. In our case, the high part of each mini block requires at most \(2\ell = O(w)\) bits and is stored using the data structure of Theorem 6 from [17] that allows to address and allocate the high part of a mini block in \(O(1)\) worst-case time. The low part of a mini block is instead stored using the data structure of Corollary 3 from [24] that supports \(\text{Access}\) in \(O(1)\) and \(\text{Insert}/\text{Delete}\) in \(O(\ell')\) worst-case time for any fixed positive \(\epsilon < 1\).

### 5.2 Space Analysis

The space required by the introduced layout will be clearly given by the contribution of:

- the data structures \(Y\) and \(P\) used in the upper level and the data structures \(T\) of Lemma 5 used in the lower level;
- the cost of representation of the mini blocks encoded with Elias-Fano;
- the overhead given by the mini blocks memory management.
In the following we separately analyze each contribution.

The space taken by the data structures $\mathcal{Y}$ and $\mathcal{P}$ in the upper level is $O\left(\frac{n}{\log n} \log u\right) = o(n)$ bits. All the data structures $T$ of Lemma 5 require $O\left(\frac{n}{\log n} \log^2 n \log \log n\right) = o(n)$ bits too.

We now analyze the space taken by the encoding of the mini blocks. Since the universe of representation of a mini block could be as large as the one of its comprising block, i.e., $u$, storing the lower bounds of the mini blocks in order to use reduced universes (as already done for the blocks), would require $O(\frac{u}{\ell} \log u)$ bits, which is too much. In what follows we show that it is not necessary to re-map the mini blocks using Property 1, hence these are kept encoded with the universe relative to their comprising block, if we carefully set the number of bits required to represent each low part in the Elias-Fano space bound (2). As pointed out previously, each low part in the Elias-Fano representation of a sequence $S(n, u)$ is encoded using $\lceil\log\frac{u}{2}\rceil$ bits, which is the number of bits needed to encode the average gap $u/n$ of $S$. The number of bits for the average gap of a block is therefore $\lceil m \rceil = \lceil \log \frac{u}{2\log^2 n} \rceil$.

The idea is to choose a number of bits $\lceil m' \rceil$ for the encoding of the average gap of the mini blocks such that $\lceil m' \rceil = \lceil m \rceil$ for a sufficiently long sequence of $p$ insertions/deletions. After $p$ insertions/deletions have been performed, we rebuild the mini blocks using $\lceil m \rceil$ bits for the average gap. In other words, we want to guarantee that encoding the mini blocks with $\lceil m' \rceil$ bits for the average gap, instead of $\lceil m \rceil$, does not introduce any extra space. Since $m'$ lies in the interval $[l, r] = [\lceil \log \frac{u}{2\log^2 n} \rceil, \lceil \log \frac{u}{2\log^2 n-p} \rceil]$, $m'$ must be chosen in order to satisfy $\lceil m \rceil - 1 < m' < \lceil m \rceil$, which indeed implies $\lceil m' \rceil = \lceil m \rceil$. Precisely, we satisfy this condition by fixing $m' = m + \theta$ with $\lceil m \rceil - l < \pm \theta < \lceil m \rceil - r + 1$. To derive this condition, we distinguish three possible cases.

1. $[l, r] \subset [(\lceil m \rceil - 1, \lceil m \rceil)]$. In this case the condition $\lceil m \rceil - 1 < m' < \lceil m \rceil$ is already satisfied.

   The other two cases are symmetric.

2. $[l] = [\lceil m \rceil - 1]$. In this case we set $m' = m + \theta$. To let $\lceil m \rceil - 1 < m' < \lceil m \rceil$ holds, $\theta$ must be at least $\lceil m \rceil - l$ and at most $\lceil m \rceil + 1 - r$. 

3. $[r] = [\lceil m \rceil + 1]$. In this case we set $m' = m - \theta$. To let $\lceil m \rceil - 1 < m' < \lceil m \rceil$ holds, $\theta$ must be at least $r - \lceil m \rceil - 1$ and at most $l - \lceil m \rceil$.

Cases 2. and 3. together yield the condition $\lceil m \rceil - l < \pm \theta < \lceil m \rceil - r + 1$.

Finally, we have to determine the proper number $p$ of insertions/deletions before triggering the rebuilding of the mini blocks in order to attain to optimal insert/delete ammortized time $O(\ell)$. As blocks are of size $\Theta(\ell \log^2 n)$, $p$ is chosen to be $O(\log^2 n)$.

The techniques used to manage the memory allocation for the mini blocks introduce an overall redundancy of $o(n)$ bits. Precisely, the data structure of Theorem 6 from [17] has an overhead of $O(w^4 + \frac{n}{\log n} \log^2 w) = o(n)$ bits, while the one of Corollary 3 from [24] uses $o(n)$ bits by choosing a proper positive $\epsilon < 1$.

In conclusion, by the above discussion and the use of Property 1, the space taken by the mini blocks can be safely upper bounded by $EF(S(n, u))$ and the redundancy sums up to $o(n)$ bits, so that the whole data structure requires $EF(S(n, u)) + o(n)$ bits of space.

5.3 Operations

In this subsection we describe how the operations of Theorem 4 are implemented. As stated before, $\ell$ is a short-hand for $\log n/\log \log n$.

To Access the $i$-th integer, we first resolve Search($i$) on $\mathcal{P}$ in $O(\ell)$: Search($i$) = $j$ indicates that the $j$-th block contains the $i$-th integer given that $\text{Sum}(j-1) < i \leq \text{Sum}(j)$, where $\text{Sum}(j)$ equals the sum of the sizes of the first $j$ blocks. We then follow the pointer stored in
the \(j\)-th leaf of \(P\), which points to the data structure \(T_j\). We finally \textbf{Access} the integer \(x\) of index \(i - \text{Sum}(j - 1)\) from \(T_j\) in \(O(\log \log n)\) and return \(x + f_j\). The overall complexity is, therefore, \(O(1)\). To \textbf{Insert/}Delete an integer \(x\), we perform the following steps: 1. identify the proper data structure \(T_j\) by resolving a partial \textbf{Successor}(\(x\)) query on \(Y\) in \(O(\log \log n)\) and following the pointer retrieved at the identified leaf of \(Y\); 2. identify the correct mini block by \textbf{Search}(\(x - f_j\)) in \(T_j\) in \(O(\log \log n)\); 3. \textbf{Insert/}Delete \(x - f_j\) in \(T_j\) by rebuilding the proper mini block in \(\Theta(\ell)\); 4. update \(P\) in \(O(1)\). During the third step, split or merge of a mini block can happen and it is handled in \(O(1)\) worst-case time by the data structure \(T_j\); rebuilding of the mini blocks can happen as pointed out in the previous section and it is handled in \(O(1)\) amortized time. If split/merge of a block happens, the lower bound of the block is inserted/removed from \(Y\) in \(O(\log \log n)\) time. The overall complexity is, therefore, \(O(1)\) amortized. The query \textbf{Predecessor}(\(x\)) is supported as follows (\textbf{Successor}(\(x\)) runs in a similar way). We identify the proper data structure \(T_j\) in \(O(\log \log n)\) by answering a partial \textbf{Predecessor}(\(x\)) query on \(Y\) and following the pointer retrieved at the identified leaf of \(Y\). Then we identify the proper mini block by \textbf{Search}(\(x - f_j\)) in \(T_j\) in \(O(\log \log n)\) time. We finally return \(f_j + \textbf{Predecessor}(x - f_j)\) by binary searching on the identified mini block. The overall complexity is \(O(\log \log n)\) worst-case. The minimum and maximum elements of \(S\) are stored uncompressed using \(\Theta(\log u)\) bits and returned when requested in \(O(1)\). Upon insertion/deletions these are updated as needed.

6 Conclusions

In this paper we have shown how the Elias-Fano representation of a monotone integer sequence \(S\) can be adapted to obtain optimal data structures in terms of query time and almost optimal in terms of space. In particular, when integers are drawn from a polynomial universe of size \(u = n^\gamma\), for any \(\gamma = \Theta(1)\), our data structures take the same asymptotic space of the plain, static, Elias-Fano representation, i.e., \(\text{EF}(S(n, u)) + o(n)\) bits and support: 1. static \textbf{Predecessor}/\textbf{Successor} queries in optimal worst-case time \(O(\min\{1 + \log \frac{u}{n}, \log \log n\})\) (Section 3); 2. a \(O(1)\) worst-case amount of work for \textbf{Append} when integers are inserted in sorted order (Section 4); 3. \textbf{Access} in optimal \(O(\log n/\log \log n)\) worst-case time, \textbf{Insert/}Delete in optimal \(O(\log n/\log \log n)\) amortized time, \textbf{Predecessor}/\textbf{Successor} queries in optimal \(O(\min\{1 + \log \frac{u}{n}, \log \log n\})\) worst-case time (Section 5).

As a last note, we observe that the data structure described in Section 5 allows us to support all operations in time \(O(\log \log u)\) when \textit{non}-polynomial universes are considered, i.e., when \(n\) and \(u\) are not necessarily related by means of the formula \(u = n^\gamma\) for any \(\gamma = \Theta(1)\). In this setting, the data structure of Lemma 5 will take \(O(\text{polylog} u \cdot \log \log u)\) bits and operate in \(O(\log \log u)\) time. In order to guarantee an overall redundancy of \(o(n)\) bits, we let mini blocks be of size \(\Theta((\log \log u)^2)\) and group \(O(\log^2 u)\) consecutive mini blocks into a block. The high part of a mini block fits into one machine word, whereas we can insert/delete a low part in \(O((\log \log u)^2)\) for Corollary 3 of [24], which is \(O(\log \log u)\) as soon as \(\epsilon < \frac{1}{2}\). Therefore, the following corollary matches the asymptotic time bounds of \(y\)-fast tries and van Emde Boas trees but in almost optimally compressed space.

\textbf{Corollary 6.} There exists a data structure representing an ordered set \(S(n, u)\) of \(n\) integers drawn from a universe of size \(u\) that takes \(\text{EF}(S(n, u)) + o(n)\) bits of space and supports: \textbf{Access} and \textbf{Predecessor}/\textbf{Successor} queries in \(O(\log \log u)\) worst-case; \textbf{Insert/}Delete in \(O(\log \log u)\) amortized and \textbf{Minimum/}\textbf{Maximum} in \(O(1)\).

Dynamic Elias-Fano Representation

Synergistic Solutions on MultiSets

Abstract

Karp et al. (1988) described Deferred Data Structures for Multisets as “lazy” data structures which partially sort data to support online rank and select queries, with the minimum amount of work in the worst case over instances of size $n$ and number of queries $q$ fixed. Barbay et al. (2016) refined this approach to take advantage of the gaps between the positions hit by the queries (i.e., the structure in the queries). We develop new techniques in order to further refine this approach and take advantage all at once of the structure (i.e., the multiplicities of the elements), some notions of local order (i.e., the number and sizes of runs) and global order (i.e., the number and positions of existing pivots) in the input; and of the structure and order in the sequence of queries. Our main result is a synergistic deferred data structure which outperforms all solutions in the comparison model that take advantage of only a subset of these features. As intermediate results, we describe two new synergistic sorting algorithms, which take advantage of some notions of structure and order (local and global) in the input, improving upon previous results which take advantage only of the structure (Munro and Spira 1979) or of the local order (Takaoka 1997) in the input; and one new multiselection algorithm which takes advantage of not only the order and structure in the input, but also of the structure in the queries.

1 Introduction

Consider a multiset $M$ of size $n$. The multiplicity of an element $x$ of $M$ is the number $m_x$ of occurrences of $x$ in $M$. We call the distribution of the multiplicities of the elements in $M$ the input structure. As early as 1976, Munro and Spira [19] described a variant of the algorithm MergeSort using counters, which optimally takes advantage of the input structure when sorting a multiset $M$ of $n$ elements. Munro and Spira measure the “difficulty” of the instance in terms of the “input structure” by the entropy function $H(m_1, \ldots, m_\sigma) = \sum_{i=1}^{\sigma} \frac{m_i}{n} \log \frac{n}{m_i}$.

where \( \sigma \) is the number of distinct elements in \( \mathcal{M} \) and \( m_1, \ldots, m_\sigma \) are the multiplicities of the \( \sigma \) distinct elements in \( \mathcal{M} \) (such that \( \sum_{i=1}^{\sigma} m_i = n \)), respectively. The time complexity of the algorithm is within \( O(n(1 + H(m_1, \ldots, m_\sigma))) \subseteq O(n(1 + \log \sigma)) \subseteq O(n \log n) \).

Any array \( \mathcal{A} \) representing a multiset lists its element in some order, which we call the *input order* and denote by a tuple. Maximal sorted subblocks in \( \mathcal{A} \) are a local form of input order and are called *runs* [16]. As early as 1973, Knuth [16] described a variant of the algorithm MergeSort using a prepossessing step taking linear time to detect runs in the array \( \mathcal{A} \). Takaoka [20] described a new sorting algorithm that optimally takes advantage of the distribution of the sizes of the runs in the array \( \mathcal{A} \), which yields a time complexity within \( O(n(1 + H(r_1, \ldots, r_\rho))) \subseteq O(n(1 + \log \rho)) \subseteq O(n \log n) \), where \( \rho \) is the number of runs in \( \mathcal{A} \) and \( r_1, \ldots, r_\rho \) are the sizes of the \( \rho \) runs in \( \mathcal{A} \) (such that \( \sum_{i=1}^{\rho} r_i = n \)), respectively.

Given an element \( x \) of a multiset \( \mathcal{M} \) and an integer \( j \in [1..n] \), the *rank* \( \text{rank}(x) \) of \( x \) is the number of elements smaller than \( x \) in \( \mathcal{M} \), and *selecting* the \( j \)-th element in \( \mathcal{M} \) corresponds to computing the value \( \text{select}(j) \) of the \( j \)-th smallest element (counted with multiplicity) in \( \mathcal{M} \). Those operations are central to the navigation of the Burrows-Wheeler transform [17] of a text when searching for occurrences of a pattern in it. As early as 1961, Hoare [12] showed how to support *rank* and *select* queries in average linear time, a result later improved to worst case linear time by Blum et al. [7]. Twenty years later, Dobkin and Munro [10] described a MultiSelection algorithm that supports several *select* queries and whose running time is optimal in the worst case over all multisets of size \( n \) and all sets of \( q \) queries hitting positions in the multisets separated by *gaps* (differences between consecutive *select* queries in sorted order) of sizes \( g_0, \ldots, g_q \). Karp et al. [15] further extended Dobkin and Munro’s result [10] to the online context, where the multiple *rank* and *select* queries arrive one by one. They called their solution a Deferred Data Structure and describe it as “lazy”, as it partially sorts data, performing the minimum amount of work necessary in the worst case over all instances for a fixed \( n \) and \( q \). Barbay et al. [2] refined this result by taking advantage of the gaps between the positions hit by the queries (i.e., the *query structure*).

This suggests the following questions:

1. Is there a sorting algorithm for multisets which takes the best advantage of both its *input order* and its *input structure* in a synergistic way, so that it performs as good as previously known solutions on all instances, and much better on instances where it can take advantage of both at the same time?

2. Is there a multiselection algorithm and/or a deferred data structure for answering *rank* and *select* queries which takes the best advantage not only of both of those notions of easiness in the input, but also of notions of easiness in the queries, such as the *query structure* and the *query order*?

We answer both questions affirmatively: In the context of Sorting, this improves upon both algorithms from Munro and Spira [19] and Takaoka [20]. In the context of MultiSelection and Deferred Data Structure for *rank* and *select* on Multisets, this improves upon Barbay et al.’s results [2] by adding three new measures of difficulty (input order, input structure and query order) to the single one previously considered (query structure). Additionally, we correct the analysis of the Sorted Set Union algorithm by Demaine et al. [9] (Section 2.2), and we define a simple yet new notion of “global” input order (Section 2.4), not mentioned in previous surveys [11, 18] nor extensions [3].

We present our results incrementally, each building on the previous one, such that the most complete and complex result is in Section 4. In Section 2 we describe how to measure the interaction of the order (local and global) with the structure in the input, and two new synergistic Sorting algorithms based on distinct paradigms (i.e., merging vs
splitting) which take advantage of both the input order and structure. We refine the second of those results in Section 3 with the analysis of a MultiSelection algorithm which takes advantage of not only the order and structure in the input, but also of the query structure, in the offline setting. In Section 4 we analyze an online Deferred Data Structure taking advantage of the order and structure in the input on one hand, and of the order and structure in the queries on the other hand. We conclude with a discussion of our results in Section 5.

2 Sorting Algorithms

We review in Section 2.1 the algorithms MergeSort with Counters described by Munro and Spira [19] and Minimal MergeSort described by Takaoka [20]: each takes advantage of distinct features in the input. In Sections 2.2 and 2.3, we describe two synergistic Sorting algorithms, which outperform both MergeSort with Counters and Minimal MergeSort by taking advantage of both the order (local and global) and the structure in the input, in a synergistic way.

2.1 Known Algorithms

The algorithm MergeSort with Counters described by Munro and Spira [19] is an adaptation of the traditional sorting algorithm MergeSort that optimally takes advantage of the input structure when sorting a multiset \( \mathcal{M} \) of size \( n \). The algorithm divides \( \mathcal{M} \) into two parts of equal size, sorts both parts recursively, and then merges the two sorted lists. When two elements of same value \( v \) are found, one is discarded and a counter holding the number of occurrences of \( v \) is updated. Munro and Spira measure the “difficulty” of the instance in terms of the input structure by the entropy function

\[
H(m_1, \ldots, m_\sigma) = \sum_{i=1}^{\sigma} \frac{m_i}{n} \log \frac{n}{m_i},
\]

where \( \sigma \) is the number of distinct elements in \( \mathcal{M} \) and \( m_1, \ldots, m_\sigma \) are the multiplicities of the \( \sigma \) distinct elements in \( \mathcal{M} \) (such that \( \sum_{i=1}^{\sigma} m_i = n \), respectively. The time complexity of the algorithm is then within \( O(n(1 + H(m_1, \ldots, m_\sigma))) \subseteq O(n(1 + \log \sigma)) \subseteq O(n \log n) \).

The algorithm Minimal MergeSort described by Takaoka [20] optimally takes advantage of the local input order, as measured by the decomposition into runs when sorting an array \( A \) of size \( n \). The main idea is to detect the runs first and then merge them pairwise. The runs are detected in linear time. Merging the two shortest runs at each step further reduces the number of comparisons, making the running time of the merging process adaptive to the entropy of the sequence formed by the sizes of the runs. If the array \( A \) is formed by \( \rho \) runs and \( r_1, \ldots, r_\rho \) are the sizes of the \( \rho \) runs (such that \( \sum_{i=1}^{\rho} r_i = n \)), then the algorithm sorts \( A \) in time within \( O(n(1 + H(r_1, \ldots, r_\rho))) \subseteq O(n(1 + \log \rho)) \subseteq O(n \log n) \).

The algorithms MergeSort with Counters and Minimal MergeSort are incomparable, in the sense that neither one performs always better than the other. Simple modifications and combinations of these algorithms do not take full advantage of both the local input order and the input structure (see the extended version [5] for detailed counter examples).

In the following sections we describe two sorting algorithms that take the best advantage of both the order (local and global) and structure in the input all at once when sorting a multiset. The first one is a straightforward application of previous results, while the second one prepares the ground for the MultiSelection algorithm (Section 3) and the Deferred Data Structures (Section 4), which take advantage of the order (local and global) and structure in the input and of the order and structure in the queries.
Synergistic Solutions on MultiSets

2.2 “Kind-of-new” Sorting Algorithm DLM Sort

In 2000, Demaine et al. [9] described the algorithm DLM Union, an instance optimal algorithm that computes the union of \( \rho \) sorted sets. The algorithm scans the sets from left to right identifying blocks of consecutive elements in the sets that are also consecutive in the sorted union (see Figure 1 for a graphical representation of such a decomposition on a particular instance of the Sorted Set Union problem). In a minor way we refine their analysis as follows:

These blocks determine a partition \( \pi \) of the output into intervals such that any singleton corresponds to a value that has multiplicity greater than 1 in the input, and each other interval corresponds to a block as defined above. Each member \( i \) of \( \pi \) has a value \( m_i \) associated with it: if the member \( i \) of \( \pi \) is a block, then \( m_i \) is 1, otherwise, if the member \( i \) of \( \pi \) is a singleton corresponding to a value of multiplicity \( q \), then \( m_i \) is \( q \). If the instance is formed by \( \delta \) blocks of sizes \( g_1, \ldots, g_\delta \) such that these blocks determine a partition \( \pi \) of size \( \chi \) of the output whose members have values \( m_1, \ldots, m_\chi \), we express the time complexity of DLM Union as within \( \Theta(\sum_{i=1}^{\delta} \log g_i + \sum_{i=1}^{\chi} \log (m_i^\rho)) \). This time complexity is within a constant factor of the complexity of any other algorithm computing the union of these sorted sets (i.e., the algorithm is instance optimal).

We adapt the DLM Union algorithm for sorting a multiset. The algorithm DLM Sort detects the runs first through a linear scan and then applies the algorithm DLM Union. After that, transforming the output of the union algorithm to yield the sorted multiset takes only linear time. The following corollary follows from our refined analysis above:

\[\text{Corollary 1. Given a multiset } M \text{ of size } n \text{ formed by } \rho \text{ runs and } \delta \text{ blocks of sizes } g_1, \ldots, g_\delta \text{ such that these blocks determine a partition } \pi \text{ of size } \chi \text{ of the output whose members have values } m_1, \ldots, m_\chi, \text{ the algorithm DLM Sort performs within } n + O(\sum_{i=1}^{\delta} \log g_i + \sum_{i=1}^{\chi} \log (m_i^\rho)) \text{ data comparisons. This number of comparisons is optimal in the worst case over multisets of size } n \text{ formed by } \rho \text{ runs and } \delta \text{ blocks of sizes } g_1, \ldots, g_\delta \text{ such that these blocks determine a partition } \pi \text{ of size } \chi \text{ of the output whose members have values } m_1, \ldots, m_\chi.\]

While the algorithm DLM Sort answers the Question 1 from Section 1, it does not yield a MultiSelection algorithm nor a Deferred Data Structure answering Question 2. In the following section we describe another sorting algorithm that also optimally takes advantage of the local order and structure in the input, but which is based on a distinct paradigm, more suitable to such extensions.
Algorithm 1 Quick Synergy Sort

Input: A multiset $\mathcal{M}$ of size $n$
Output: A sorted sequence of $\mathcal{M}$

1: Compute the $\rho$ runs of respective sizes $(r_i)_{i \in [1..\rho]}$ in $\mathcal{M}$ such that $\sum_{i=1}^{\rho} r_i = n$;
2: Compute the median $\mu$ of the middles of the runs, note $j \in [1..\rho]$ the run containing $\mu$;
3: Find the maximum $\max_{\ell}$ (minimum $\min_r$) among the elements smaller (resp., greater) than $\mu$ in all runs except the $j$-th, starting at both ends of the runs in parallel;
4: Perform doubling searches for the value $\mu$ in all runs except the $j$-th, starting at both positions of $\mu$;
5: Perform doubling searches for the values $\max_{\ell}$ and $\min_r$ in the $j$-th run, starting at the position of $\mu$;
6: Recurse on the elements smaller than or equal to $\max_{\ell}$ and on the elements greater than or equal to $\min_r$.

2.3 New Sorting Algorithm Quick Synergy Sort

Given a multiset $\mathcal{M}$, the algorithm Quick Synergy Sort identifies the runs in linear time through a scanning process. It computes a pivot $\mu$, which is the median of the set formed by the middle elements of each run, and partitions each run by $\mu$. This partitioning process takes advantage of the fact that the elements in each run are already sorted. The insertion ranks of the pivots in the runs are identified by doubling searches [6]. It then recurses on the elements smaller than $\mu$ and on the elements greater than $\mu$. (See Algorithm 1 for a more formal description).

Definition 2 (Median of the middles). Given a multiset $\mathcal{M}$ formed by runs, the “median of the middles” is the median element of the set formed by the middle elements of each run.

The number of data comparisons performed by the algorithm Quick Synergy Sort is asymptotically the same as the number of data comparisons performed by the algorithm DLM Sort described in the previous section. We divide the proof into two lemmas. We first bound the number of data comparisons performed by all the doubling searches of the algorithm Quick Synergy Sort (i.e., steps 3 and 5 of the Algorithm 1).

Lemma 3. Let $g_1, \ldots, g_k$ be the sizes of the $k$ blocks that form the $r$-th run. The overall number of data comparisons performed by the doubling searches of the algorithm Quick Synergy Sort to find the values of the medians of the middles in the $r$-th run is within $O(\sum_{i=1}^{\rho} \log g_i)$.

Proof. Every time the algorithm finds the insertion rank of one of the medians of the middles in the $r$-th run, it partitions the run by a position separating two blocks. The doubling search steps can be represented as a tree. Each node of the tree corresponds to a step. Each internal node has two children, which correspond to the two subproblems into which the step partitions the run. The cost of the step is less than four times the logarithm of the size of the child subproblem with smaller size, because of the two doubling searches in parallel. The leaves of the tree correspond to the blocks themselves.

We prove that at each step the total cost is bounded by eight times the sum of the logarithms of the sizes of the leaf subproblems. This is done by induction over the number of steps. If the number of steps is zero then there is no cost. For the inductive step, if the number of steps increases by one, a new doubling search step is done and a leaf subproblem is partitioned into two new subproblems. At this step, a leaf of the tree is transformed into an
Consider the steps that compute the medians of the middles and the steps that find the
(see Section 2.2 for the definition of elements max comparisons performed during these steps is within
4 of the algorithm.

\[ \text{Proof.} \]
We prove this lemma by induction over the size \( \pi \) of the algorithm. Let \( \rho, \pi \), and \( \mu \) be the number of runs in \( \mathcal{M} \).

As shown in the following lemma, the overall number of data comparisons performed
during the computation of the medians of the middles (i.e., step 2 of the Algorithm 1) is
within \( O(\sum_{i=1}^{\chi} \log (\rho_{m_i}^{\rho})) \), where \( m_1, \ldots, m_{\chi} \) are the values of the member of the partition \( \pi \)
(see Section 2.2 for the definition of \( \pi \)) and \( \rho \) is the number of runs in \( \mathcal{M} \).

Consider the instance depicted in Figure 2 for an example illustrating from where the
term \( \log (\rho_{m_i}^{\rho}) \) comes. In this instance, there is a value \( v \) that has multiplicity \( m_v > 1 \) in \( \mathcal{M} \)
and the rest of the values have multiplicity 1. The elements with value \( v \) are present at the
end of the last \( m_v \) runs and the rest of the runs are formed by only one block. The elements
of the \( i \)-th run are greater than the elements of the \((i + 1)\)-th run. During the computation of the
edges of the middles, the number of data comparisons that involve elements of value \( v \)
is within \( O(\log (\rho_{m_v}^{\rho})) \). The algorithm computes the median \( \mu \) of the middles and partitions
the runs by the value of \( \mu \). In the recursive call that involves elements of value \( v \), the number
of runs is reduced by half. This is repeated until one occurrence of \( \mu \) belongs to one of the
last \( m_v \) runs. The number of data comparisons that involve elements of value \( v \) up to this
step is within \( O(m_v \log (\frac{\rho}{m_v})) = O(\log (\rho_{m_v}^{\rho})) \), where \( \log (\frac{\rho}{m_v}) \) corresponds to the number of steps
where \( \mu \) does not belong to the last \( m_v \) runs. The next recursive call will necessarily choose
one element of value \( v \) as the median of the middles.

\begin{lemma}
\text{Lemma 4. Let } \mathcal{M} \text{ be a multiset formed by } \rho \text{ runs and } \delta \text{ blocks such that these blocks determine a partition } \pi \text{ of size } \chi \text{ of the output whose members have values } m_1, \ldots, m_{\chi}. \text{ Consider the steps that compute the medians of the middles and the steps that find the elements max and min, in the algorithm Quick Synergy Sort, the overall number of data comparisons performed during these steps is within } O(\sum_{i=1}^{\chi} \log (\rho_{m_i}^{\rho})).
\end{lemma}

\textbf{Proof.} We prove this lemma by induction over the size \( \chi \) of \( \pi \) and the number of runs \( \rho \). The number of data comparisons performed by one of these steps is linear in the
number of runs in the sub-instance (i.e., ignoring all the empty sets of this sub-instance).
Let \( T(\pi, \rho) \) be the overall number of data comparisons performed during the steps 2 and
4 of the algorithm Quick Synergy Sort. We prove that \( T(\pi, \rho) \leq \sum_{i=1}^{\chi} m_i \log (\frac{\rho}{m_i}) - \rho \).
Let \( \mu \) be the first median of the middles computed by the algorithm. Let \( \ell \) and \( r \) be the number of runs that are completely to the left and to the right of \( \mu \), respectively.
Let \( b \) be the number of runs that are split in the doubling searches for the value of \( \mu \).
in all runs. Let $\pi_l$ and $\pi_r$ be the partitions determined by the blocks yielded to the left and to the right of $\mu$, respectively. Then, $T(\pi, \rho) = T(\pi_l, \ell + b) + T(\pi_r, r + b) + \rho$ because of the two recursive calls and the step that computes $\mu$. By Induction Hypothesis, $T(\pi_l, \ell + b) \leq \sum_{i=1}^{\chi} m_i \log \frac{\ell + b}{m_i} - \ell - b$ and $T(\pi_r, r + b) \leq \sum_{i=1}^{\chi} m_i \log \frac{r + b}{m_i} - r - b$. Hence, we need to prove that $\ell + r \leq \sum_{i=1}^{\chi} m_i \log \left(1 + \frac{\ell}{\ell + r}\right) + \sum_{i=1}^{\chi} m_i \log \left(1 + \frac{r}{r + b}\right)$, but this is a consequence of $\sum_{i=1}^{\chi} m_i \geq \ell + b, \sum_{i=1}^{\chi} m_i \geq r + b$ (the number of blocks is greater than or equal to the number of runs); $\ell \leq r + b, r \leq \ell + b$ (at least $\frac{n}{2}$ runs are left to the left and to the right of $\mu$); and $\log \left(1 + \frac{\ell}{\ell + b}\right)^{\ell} \geq y$ for $y \leq x$. \hfill $\triangleright$

Consider the step that performs doubling searches for the values max$_x$ and min$_x$ in the run that contains the median $\mu$ of the middles, this step results in the finding of the block $g$ that contains $\mu$ in at most $4 \log |g|$ data comparisons, where $|g|$ is the size of $g$. Combining Lemma 3 and Lemma 4 yields an upper bound on the number of data comparisons performed by the algorithm Quick Synergy Sort:

$\triangleright$ **Theorem 5.** Let $M$ be a multiset of size $n$ formed by $\rho$ runs and $\delta$ blocks of sizes $g_1, \ldots, g_\delta$ such that these blocks determine a partition $\pi$ of size $\chi$ of the output whose members have values $m_1, \ldots, m_\chi$. The algorithm Quick Synergy Sort performs within $n + O(\sum_{i=1}^{\delta} g_i, \sum_{i=1}^{\delta} \log \left(\frac{\chi}{m_i}\right))$ data comparisons on $M$. This number of comparisons is optimal in the worst case over multisets of size $n$ formed by $\rho$ runs and $\delta$ blocks of sizes $g_1, \ldots, g_\delta$ such that these blocks determine a partition $\pi$ of size $\chi$ of the output whose members have values $m_1, \ldots, m_\chi$.

We extend these results to take advantage of the global order of the multiset in a way that can be combined with the notion of runs (local order).

### 2.4 Taking Advantage of Global Order

Given a multiset $M$, a *pivot position* is a position $p$ in $M$ such that all elements in previous position are smaller than or equal to all elements at $p$ or in the following positions. In 1962, Iverson [13] described an improved version of BubbleSort [16] that identifies such pivot positions (as pair of consecutive elements that the algorithm have placed at their final positions and on which it does not make further comparisons). We show that detecting such positions also yields an improved version of QuickSort in general, and of our QuickSort-inspired solutions in particular. More formally:

$\triangleright$ **Definition 6 (Pivot positions).** Given a multiset $M = (x_1, \ldots, x_n)$ of size $n$, the “pivot positions” are the positions $p$ such that $x_a \leq x_b$ for all $a, b$ such that $a \in [1..p - 1]$ and $b \in [p..n]$.

Existing pivot positions in the input order of $M$ divide the input into subsequences of consecutive elements such that the range of positions of the elements at each subsequence coincide with the range of positions of the same elements in the sorted sequence of $M$: the more there are of such positions, the more “global” order there is in the input. Detecting such positions takes only a linear number of comparisons by applying the first phase of the algorithm BubbleSort [16], which sequentially compares the elements, from left to right in a first phase and then from right to left in a second phase. The positions of the elements that do not interchange their values during both executions are the pivot positions in $M$.

When there are $\phi$ such positions, they simply divide the input of size $n$ into $\phi + 1$ sub-instances of sizes $n_0, \ldots, n_\phi$ (such that $\sum_{i=0}^{\phi} n_i = n$). Each sub-instance $I_i$ for $i \in [0..\phi]$ then
Corollary 7. Let \( \mathcal{M} \) be a multiset of size \( n \) with \( \phi \) pivot positions. Let \( n_0, \ldots, n_\phi \) be integers such that the \( \phi \) pivot positions divide \( \mathcal{M} \) into \( \phi + 1 \) sub-instances of sizes \( n_0, \ldots, n_\phi \) (such that \( \sum_{i=0}^{\phi} n_i = n \)). Let \( \rho_i \) and \( \delta_i \) be such that each sub-instance \( I_i \) of size \( n_i \) is formed by \( \rho_i \) runs and \( \delta_i \) blocks of sizes \( g_1, \ldots, g_{\delta_i} \) such that these blocks determine a partition \( \pi_i \) of size \( \chi_i \) of the output whose members have values \( m_{i1}, \ldots, m_{i\chi_i} \) for \( i \in [0, \phi] \). There exists an algorithm that performs within \( 3n + O(\sum_{i=0}^{\phi} \{ \sum_{j=1}^{\delta_i} \log g_{ij} + \sum_{j=1}^{\delta_i} \log \left( \binom{\phi}{m_{ij}} \right) \}) \) data comparisons for sorting \( \mathcal{M} \). This number of comparisons is optimal in the worst case over multisets of size \( n \) with \( \phi \) pivot positions which divide the multiset into \( \phi + 1 \) sub-instances of sizes \( n_0, \ldots, n_\phi \) (such that \( \sum_{i=0}^{\phi} n_i = n \)) and each sub-instance \( I_i \) of size \( n_i \) is formed by \( \rho_i \) runs and \( \delta_i \) blocks of sizes \( g_1, \ldots, g_{\delta_i} \) such that these blocks determine a partition \( \pi_i \) of size \( \chi_i \) of the output whose members have values \( m_{i1}, \ldots, m_{i\chi_i} \) for \( i \in [0, \phi] \).

Next, we generalize the algorithm Quick Synergy Sort to an offline multiselection algorithm that partially sorts a multiset according to the set of select queries given as input. This serves as a pedagogical introduction to the online Deferred Data Structures for answering rank and select queries presented in Section 4.

## 3 MultiSelection Algorithm

Given a linearly ordered multiset \( \mathcal{M} \) and a sequence of ranks \( r_1, \ldots, r_q \), a multiselection algorithm must answer the queries \( \text{select}(r_1), \ldots, \text{select}(r_q) \) in \( \mathcal{M} \), hence partially sorting \( \mathcal{M} \). We describe a MultiSelection algorithm based on the sorting algorithm Quick Synergy Sort introduced in Section 2.3. This algorithm is an intermediate result leading to the Deferred Data Structure described in Section 4.

Given a multiset \( \mathcal{M} \) and a set of \( q \) select queries, the algorithm Quick Synergy MultiSelection follows the same first steps as the algorithm Quick Synergy Sort. But once it has computed the ranks of all elements in the block that contains the pivot \( \mu \), it determines which select queries correspond to elements smaller than or equal to max and which ones correspond to elements greater than or equal to min, (see Algorithm 1 for the definitions of max and min). It then recurses on both sides.

We extend the notion of blocks to the context of partial sorting. Next, we introduce the definitions of pivot blocks and selection blocks (see Figure 3 for a graphical representation of these definitions).

### Definition 8 (Pivot Blocks).
Given a multiset \( \mathcal{M} \) formed by \( \rho \) runs and \( \delta \) blocks. The “pivot blocks” are the blocks of \( \mathcal{M} \) that contain the pivots and the elements of value equals to the pivots during the steps of the algorithm Quick Synergy MultiSelection.

In each run, between the pivot blocks and the insertion ranks of the pivots, there are consecutive blocks that the algorithm Quick Synergy MultiSelection has not identified as separated blocks, because no doubling searches occurred inside them.

### Definition 9 (Selection Blocks).
Given the \( i \)-th run, formed of various blocks, and \( q \) select queries, the algorithm Quick Synergy MultiSelection computes \( \xi \) pivots in the process of answering the \( q \) queries. During the doubling searches, the algorithm Quick Synergy MultiSelection finds the insertion ranks of the \( \xi \) pivots inside the \( i \)-th run. These positions
queries performing within blocks λ the input of size applied as the first step of the multiselection algorithm. The Quick Synergy Sort algorithm compares in this supposed instance (see the proof of Lemmas 3 and 4 analyzing the would perform within the elements of one are smaller than the elements of the other one. The algorithm divides the runs into selection blocks. s = 7 is the size of the second selection block, from left to right, into which the third run is divided by the algorithm. m = 2 is the number of pivot blocks of size 1 corresponding to the pivot p₂.

determine a partition of size ξ + 1 of the i-th run where each element of the partition is formed by consecutive blocks or is empty. We call the elements of this partition “selection blocks”. The set of all selection blocks contains the set of all pivot blocks.

Using these definitions, we generalize the results proven in Section 2.3 to the more general problem of MultiSelection.

**Theorem 10.** Given a multiset M of size n formed by ρ runs and δ blocks; and q offline select queries over M corresponding to elements of ranks r₁, ..., r₉. Let ξ be the number of pivots computed by the algorithm Quick Synergy MultiSelection in the process of answering the q queries. Let s₁, ..., s₁ be the sizes of the β selection blocks determined by these ξ pivots in all runs. Let m₁, ..., m₁ be the numbers of pivot blocks corresponding to the values of the λ pivots with multiplicity greater than 1, respectively. Let p₀, ..., p₀ be the sequence where pᵢ is the number of runs that have elements with values between the pivots i and i + 1 sorted by ranks, for i ∈ [1, ξ]. The algorithm Quick Synergy MultiSelection answers the q select queries performing within $n + O \left( \sum_{i=1}^{β} \log s_i + β \log ρ - \sum_{i=1}^{λ} m_i \log m_i - \sum_{i=0}^{ξ} p_i \log p_i \right) \leq O(n \log n - \sum_{i=0}^{δ} Δ_i \log Δ_i)$ data comparisons, where $Δ_i = r_{i+1} - r_i$, $r_0 = 0$ and $r_{φ+1} = n$.

**Proof.** The pivots computed by the algorithm Quick Synergy MultiSelection for answering the queries are a subset of the pivots computed by the algorithm Quick Synergy Sort for sorting the whole multiset. Suppose that the selection blocks determined by every two consecutive pivots form a multiset $M_j$ such that for every pair of selection blocks in $M_j$ the elements of one are smaller than the elements of the other one. The algorithm Quick Synergy Sort would perform within $n + O \left( \sum_{i=1}^{β} \log s_i + β \log ρ - \sum_{i=1}^{λ} m_i \log m_i \right)$ data comparisons in this supposed instance (see the proof of Lemmas 3 and 4 analyzing the algorithm Quick Synergy Sort for details). The number of comparisons needed to sort the multisets $M_j$ is within $Θ(\sum_{i=0}^{δ} p_i \log p_i)$. The result follows.

The process of detecting the φ pre-existing pivot positions seen in Section 2.4 can be applied as the first step of the multiselection algorithm. The φ pivot positions divide the input of size n into φ + 1 sub-instances of sizes $n_0, ..., n_φ$. For each sub-instance $I_i$, for $i ∈ [0, φ]$, the multiselection algorithm determines which select queries correspond to $I_i$. 

**Figure 3** An instance of the MultiSelection problem where the multiset $M$ is formed by $ρ = 5$ runs. In each run $R$, the entry $R[i]$ is represented by a point of x-coordinate $R[i]$. The dash lines represent the answers of the two select queries. The solid vertical lines represent the positions $p_1$ and $p_2$ of the first two pivots computed by the Quick Synergy MultiSelection algorithm. The pivot blocks corresponding to the pivots $p_1$ and $p_2$ are marked by contiguous open disks. The algorithm divides the runs into selection blocks. $s = 7$ is the size of the second selection block, from left to right, into which the third run is divided by the algorithm. $m = 2$ is the number of pivot blocks of size 1 corresponding to the pivot $p_2$. 

**CPM 2017**
and applies then the steps of the algorithm Quick Synergy MultiSelection inside $I$, in order to answer these queries.

The Quick Synergy MultiSelection algorithm takes advantage of the number and sizes of the runs (i.e., the local input order), the number and positions of the pre-existing pivot positions (i.e., the global order), the multiplicities of the elements in the multiset (i.e., the input structure) and the differences between consecutive select queries in sorted order (i.e., the query structure).

In the result above, the queries are given all at the same time (i.e., offline). In the context where they arrive one at the time (i.e., online), we define a Deferred Data Structure for answering online rank and select queries, inspired by the algorithm Quick Synergy MultiSelection.

4 Rank and Select Deferred Data Structures

We describe the Full-Synergistic Deferred Data Structure that answers a set of rank and select queries, arriving one at the time, over a multiset $M$, progressively sorting $M$. This deferred data structure is based in the Quick Synergy MultiSelection algorithm described in the previous section. This data structure takes advantage of the order (local and global) and structure in the input, and of the order and structure in the queries.

By “query order”, we mean to consider the “distances” between consecutive queries. To take advantage of the query order, we introduce a data structure that finds the nearest pivots to the left and to the right of a position $p \in [1..n]$, while taking advantage of the distance between the position of the last computed pivot and $p$, as measured by the number of computed pivot blocks between the two positions. For that we use a finger search tree [8] maintaining fingers (i.e., pointers) to elements in the search tree and supporting efficient updates and searches in the vicinity of those. Brodal [8] described an implementation of finger search trees that searches for an element $x$, starting the search at the element given by the finger $f$ in time within $O(\log d)$, where $d$ is the distance between $x$ and $f$ in the set (i.e., the difference between $\text{rank}(x)$ and $\text{rank}(f)$ in the set). This operation returns a finger to $x$ if $x$ is contained in the set, otherwise a finger to the largest element smaller than $x$ in the set. This implementation supports the insertion of an element $x$ immediately to the left or to the right of a finger in worst-case constant time.

Given a multiset $M$ of size $n$, the Full-Synergistic Deferred Data Structure includes a finger search tree $F_{\text{select}}$, in which it marks the elements in $M$ that have been computed as pivots when it answers the online queries. For each pivot $p$ in $F_{\text{select}}$, the data structure stores pointers to the insertion ranks of $p$ in each run, to the beginning and to the end of the block $g$ to which $p$ belongs, and to the position of $p$ inside $g$. This finger search tree is also used to find the two successive pivots between which the query fits.

Once a pivot block $g$ is computed, every element in $g$ is a valid pivot for the rest of the elements in $M$. In order to capture this idea, we modify the finger search tree $F_{\text{select}}$ so that it contains the pivot blocks (i.e., a sequence of consecutive values) instead of singleton pivots. This modification allows the Full-Synergistic Deferred Data Structure to answer select queries, taking advantage of the structure and order in the queries and of the structure and order in the input. But in order to answer rank queries taking advantage of the features in the queries and the input, the data structure needs another finger search tree $F_{\text{rank}}$. In $F_{\text{rank}}$, the data structure stores, for each block $g$ identified, the value of one of the elements in $g$, and pointers in $M$ to the beginning and to the end of $g$, and in each run to the position where the elements of $g$ partition the run.
Figure 4 The state of the Full-Synergistic Deferred Data Structure on an instance where the multiset $M$ is formed by $\rho = 5$ runs. In each run, the entry $M[i]$ is represented by a point of $x$-coordinate $M[i]$. The dash lines represent the positions $q_1$ and $q_2$ of the answers of the first two queries. The solid vertical lines represent the positions $p_1, p_2$ and $p_3$ of the first three pivot computed by the Full-Synergistic Deferred Data Structure. The pivot blocks corresponding to the pivots $p_1, p_2$ and $p_3$ are marked by contiguous open disks. $d = 4$ is the distance (i.e., the number of computed pivot blocks) between the queries $q_1$ and $q_2$. If $q_1$ is a rank query, then $g = 4$ is the size of the identified block that contains the answer of the query $q_1$.

Theorem 11. Consider a multiset $M$ of size $n$ formed by $\rho$ runs and $\delta$ blocks. Let $\gamma$ and $\tau_1, \ldots, \tau_q$ be the number of pivot blocks computed by the Full-Synergistic Deferred Data Structure in the process of answering $q$ online rank and select queries over $M$, and the ranks of the elements corresponding to these queries, respectively. Let $s_1, \ldots, s_\beta$ be the numbers of pivot blocks corresponding to the values of the $\lambda$ pivots with multiplicity greater than 1, respectively. Let $\rho_0, \ldots, \rho_\gamma$ be the sequence where $\rho_i$ is the number of runs that have elements with values between the elements in the blocks $i$ and $i + 1$ sorted by ranks, for $i \in [1..\gamma]$. Let $d_1, \ldots, d_{q-1}$ be the sequence where $d_j$ is the number of computed pivot blocks between the block that answers the $(j-1)$-th query and the one that answers the $j$-th query before starting the steps to answer the $j$-th query, for $j \in [2..q]$. Let $u$ and $g_1, \ldots, g_u$ be the number of rank queries and the sizes of the computed and searched pivot blocks in the process of answering the $u$ rank queries, respectively.

The Full-Synergistic Deferred Data Structure answers the $q$ online queries by performing within $n + O(\sum_{i=1}^\beta \log s_i + \beta \log \rho - \sum_{i=1}^\lambda \log m_i \log m_i - \sum_{i=0}^\gamma \log \rho_i \log \rho_i + \sum_{i=1}^{q-1} \log d_i + \sum_{i=1}^u \log g_i) \leq O(n \log n - \sum_{i=0}^q \Delta_i \log \Delta_i + q \log n)$ data comparisons, where $\rho_0 = 0$, $\rho_{q+1} = n$, and $\Delta_i = \tau_{i+1} - \tau_i$, for all $i \in [1..n]$.

Proof. The algorithm answers a new select$(i)$ query by searching in $F_{select}$ for the nearest pivot to the left and right of the query position $i$. If $i$ is contained in an element of $F_{select}$, then the block $g$ that contains the element in the position $i$ has already been computed. If $i$ is not contained in an element of $F_{select}$, then the returned finger $f$ points the nearest block $b$ to the left of $i$. The block that follows $f$ in $F_{select}$ is the nearest block to the right of $i$. It then applies the same steps as the algorithm Quick Synergy MultiSelection in order to answer the query. Given $f$, the algorithm inserts in $F_{select}$ each pivot block computed in the process of answering the query in constant time, and stores the respective pointers to positions in $M$. In $F_{rank}$ the algorithm searches for the value of one of the elements in $b$. Once the algorithm obtains the finger returned by this search, the algorithm inserts in $F_{rank}$ the value of one of the elements of each pivot block in constant time, and stores the respective pointers to positions in $M$ (see Figure 4 for a graphical representation of some of the parameters used in the analysis).
The algorithm answers a new rank$(x)$ query by finding the selection block $s_j$ in the $j$-th run such that $x$ is between the smallest and the greatest value of $s_j$ for all $j \in [1..\rho]$. For that the algorithm searches for the value $x$ in $F_{\text{rank}}$. The number of data comparisons performed by this searching process is within $O(\log d)$, where $d$ is the number of blocks in $F_{\text{rank}}$ between the last inserted or searched block and the returned finger $f$. Given the finger $f$, there are three possibilities for the rank $r$ of $x$: (i) $r$ is between the ranks of the elements at the beginning and at the end of the block pointed by $f$, (ii) $r$ is between the ranks of the elements at the beginning and at the end of the block pointed by the finger following $f$, or (iii) $r$ is between the ranks of the elements in the selection blocks determined by $f$ and the finger following $f$. In the cases (i) and (ii), a binary search inside the block yields the answer of the query. In the case (iii), the algorithm applies the same steps as the algorithm Quick Synergy MultiSelection in order to compute the median $\mu$ of the middles, and partitions the selection blocks by $\mu$. The algorithm then decides to which side $x$ belongs. Similar to the algorithm for answering a select query, the data structure inserts in $F_{\text{select}}$ every block computed in the process of answering the rank query.

The process of detecting the $\phi$ pivot positions seen in Section 2.4 allows the Full-Synergistic Deferred Data Structure to insert these pivots in $F_{\text{select}}$ and $F_{\text{rank}}$. For each pivot position $p$ in $F_{\text{select}}$ and $F_{\text{rank}}$, the data structure stores pointers to the end of the runs detected on the left of $p$; to the beginning of the runs detected on the right of $p$; and to the position of $p$ in the multiset. This concludes the description of our synergistic results. In the next section, we discuss how these results relate to various past results and future work.

5 Discussion

Kalogi et al.'s multiselection algorithm [14] and Barbay et al's deferred data structure [2] use the very same concept of runs as the one described in this work. The difference is, we describe algorithms that detect the existing runs in the input in order to take advantage of them, while the algorithms described by those previous works do not take into consideration any pre-existing runs in the input, and rather build and maintain such runs as a strategy to minimize the number of comparisons performed while partially sorting the multiset. We leave the combination of both approaches as a topic for future work, which could probably shave a constant factor off the number of comparisons performed by the Sorting and MultiSelection algorithms and by the Deferred Data Structures supporting rank and select queries on multisets.

Barbay and Navarro [3] described how any Sorting algorithm taking advantage of specificities in the input, directly implies a compressed encoding for permutations. By using the similarity of the execution tree of the algorithm MergeSort with the Wavelet Tree data structure, they described a compressed data structure for permutations taking advantage of the local order, i.e., using space proportional to $H(r_1,\ldots,r_\rho)$ and supporting direct access (i.e. $\pi()$) and inverse access (i.e. $\pi^{-1}()$) in worst time within $O(1 + \log \rho)$ and average time within $O(1 + H(r_1,\ldots,r_\rho))$. We leave as future work the extension of our work into a compressed data structure for multisets taking advantage of both its structure and (local and global) order.

Another perspective is to generalize the synergistic results to related problems in computational geometry: Karp et al. [15] defined the first deferred data structure not only to support rank and select queries on multisets, but also to support online queries in a deferred way on Point Membership in a Convex Hull in two dimensions and online Dominance
queries on sets of multi-dimensional vectors. Preliminary results [4] show that one can refine the results from Karp et al. [15] to take advantage of the blocks between queries (i.e., the structure in the queries) as Barbay et al. [2] did for multisets; but also of the relative position of the points (i.e., the structure in the input) as Afshani et al. [1] did for Convex Hulls and MAXIMA; of the order in the points (i.e., the order in the input), as computing the convex hull in two dimensions takes linear time if the points are sorted; and potentially of the order in the queries.
