SUMMARY

Background: Preliminary trials of probiotics in preventing recurrent chronic pouchitis have been encouraging.
Aim: To investigate the efficacy of Lactobacillus GG supplementation as primary therapy for ileal pouch inflammation, and its effect on the microbial flora.
Methods: Twenty patients, with a previous history of pouchitis and endoscopic inflammation, were recruited for a prospective, randomized, double-blind, placebo-controlled trial of Lactobacillus GG supplementation (10 LGG, 10 placebo) in two gelatine capsules [(0.5–1) × 10¹⁰ colony-forming units/capsule] b.d. for 3 months. Quantitative bacterial culture of fresh faecal samples and biopsies taken from the pouch and afferent limb was performed before and after supplementation.
Results: Lactobacillus GG supplementation changed the pouch intestinal flora by increasing the ratio of total faecal lactobacilli to total faecal anaerobes (P = 0.03) and enhancing the frequency of lactobacilli-positive cultures in the pouch and afferent limb mucosal biopsy samples. However, only 40% of patients were colonized with Lactobacillus GG. No differences were observed between the groups with regard to the mean pouchitis disease activity index or the total anaerobes or aerobes of faecal or tissue biopsy samples.
Conclusions: A single-strain probiotic bacterium supplementation of Lactobacillus GG changed the pouch intestinal bacterial flora, but was ineffective as primary therapy for a clinical or endoscopic response. More clinical trials are needed to evaluate the right placement and dosage of probiotics within a treatment regimen for pouchitis.

INTRODUCTION

The most significant late complication after restorative proctocolectomy and ileal pouch–anal anastomosis is pouchitis, which, depending on the diagnostic criteria used and the follow-up time after surgery, occurs in 20–59% of patients.¹–³ Most episodes of pouchitis are single attacks usually responding to metronidazole or antibiotic combination therapy.⁴ The good response to antibiotic therapy directed against anaerobic bacteria suggests a role for the bacterial flora in the pouch.

Probiotic bacteria are non-pathogenic micro-organisms belonging to the natural gastrointestinal flora that confer a health benefit by altering the indigenous microflora.⁵, ⁶ Lactobacilli, bifidobacteria and other members of the resident microflora are commonly selected as probiotics. They can influence intestinal physiology, either directly or indirectly through modulation of the endogenous ecosystem or immune system.⁷ Preliminary trials of probiotics in the maintenance treatment of chronic pouchitis have been encouraging.⁸ Lactobacillus rhamnosus GG is a safe probiotic bacterium, relatively resistant to acid and bile, which adheres in vitro to epithelial cells and intestinal mucus,⁹ transiently colonizes the human intestine,¹⁰ elaborates an antimicrobial substance¹¹ and transiently colonizes the human intestine.¹², ¹³ Lactobacillus GG has
shown promise in the treatment of rotavirus, travel-
ners and relapsing Clostridium difficile diarrhoea.
Although recent studies have provided evidence that
beneficial probiotic bacteria can reduce relapses of
chronic pouchitis, many questions remain with regard
to the dosage required and the selection of the probiotic
strain: do we need probiotic cocktails together with
antibiotics for a clinical response or is a single probiotic
strain effective?
The aim of this study was to evaluate the clinical efficacy
of a commercially available single-strain Lactobacillus
GG preparation on ileal pouch–anal inflammation in
patients with restorative proctocolectomy for ulcerative
colitis. The colonization and influence of Lactobacillus GG
on the pouch microbial flora were determined.

MATERIALS AND METHODS

Subjects

We analysed the medical histories of all ulcerative colitis
patients (n = 104; male to female ratio, 53/51; mean
age, 45.2 years; range, 23–70 years) who underwent
restorative proctocolectomy with an ileal J pouch–anal
anastomosis between 1985 and 1994 at the Depart-
ment of Surgery, Helsinki University Central Hospital,
and who had a control follow-up endoscopy between
1997 and 1999. Histories included clinical symptoms,
endoscopic and histological findings in previous follow-
up endoscopies and the follow-up time after ileal pouch–
anal anastomosis. The diagnosis of ulcerative colitis had
been established in all subjects by standard endoscopic,
histological and radiological methods, and by clinical
assessment and proctocolectomy specimens.

Of the 104 patients, 44 had been treated once or
several times for clinical symptoms indicative of pouch-
itis, and had endoscopic and histological inflammation
in the latest follow-up endoscopy. Based on these
criteria, all 44 subjects were recruited into a pros-
pective, randomized, double-blind, placebo-controlled
clinical trial of Lactobacillus GG (Lactobacillus rhamnosus GG,
ATCC53103) supplementation for 3 months. The exclu-
sion criteria were as follows: (i) refusal to participate;
(ii) antibiotic therapy within 1 month; (iii) active
chronic pouchitis (intermittent or continuous medical
treatment) or symptoms [fever, bleeding, increased
number of stools (> 2/day within 1 week) indicative
of an acute exacerbation of pouchitis; (iv) pregnancy.
A total of 22 study subjects were enrolled.

All patients gave written informed consent, and the
study protocol was approved by the Ethics Committee of
the hospital.

Lactobacillus GG supplementation

Subjects were randomized to receive treatment with
gelatine capsules (Gefilus, Valio Ltd, Helsinki, Finland)
containing Lactobacillus GG [(0.5–1) × 10^10 colony-
forming units/capsule], with microcrystalline cellulose
as a filling material, or microcrystalline cellulose only
as a placebo. Each subject received four capsules of
Lactobacillus GG (or placebo) per day as two equal doses
for 3 months. Subjects were asked not to eat probiotic
dairy products during the supplementation period.

Clinical assessment

All patients were examined by a single investigator (JK)
for the recording of clinical symptoms (stool frequency/
24 h, abdominal cramps, rectal bleeding, fever) and
medication.

Fresh faecal samples were collected prior to endoscopy.
The pouch was emptied with water enemas. During
flexible pouch endoscopy before biopsy, the mucosa was
carefully rinsed with sterile water under direct visual
control to remove all possible faecal contamination. Five
separate tissue biopsy specimens (three for bacterial
culture and two for histology) were obtained from the
pouch and live from the afferent limb above the pouch.
These specimens were taken from the regions exhibiting
active inflammation endoscopically. Staples and suture
lines were avoided. Tissue biopsy samples were thor-
oughly rinsed with downward jets of sterile saline and
placed in a Stuart transport tube.

All histological biopsy specimens were reviewed in a
blind fashion by one pathologist (AK). Serial sections of
formalin-fixed, paraffin-embedded tissue were stained
with haematoxylin and eosin. The haematoxylin and
eosin-stained sections were scored on a scale of 0
(absent) to 3 (severe) for the degree of acute inflamma-
tion (polymorphonuclear leucocyte infiltration, ulcers)
and for the degree of villous atrophy, according to the
criteria of Moskowitz et al.17

Bacteriological studies

Bacteriological samples were immediately transported to
the laboratory and processed within 2 h. Specimens were
weighed and ground in thioglycolate medium (1 : 10) in a tissue grinder. Faecal samples were homogenized, their pH measured (Benchtop 420 pH Meter, Orion, Beverly, MA, USA) and serially diluted \((10^{-1} – 10^{-7})\) in pre-reduced peptone–yeast extract broth (pH 7.0). Appropriate dilutions and aliquots of the homogenates were plated on to several selective and non-selective agar media for the isolation of aerobic and anaerobic microbes. MRS (deMan Rogosa and Sharpe, Merck, Darmstadt, Germany) agar was used for the isolation of lactobacilli, Brucella agar supplemented with haemin and vitamin K\(_1\) for total counts of anaerobic bacteria, and blood agar (5% sheep blood) for total counts of aerobic bacteria. MRS and Brucella plates were incubated in anaerobic jars filled with a gas mixture (80% N\(_2\), 10% CO\(_2\), 10% H\(_2\)) and blood plates in a 7% CO\(_2\) atmosphere, both at 37°C for up to 14 days. Total counts of the main groups of aerobic and anaerobic bacteria and yeast were enumerated. Different colony morphotypes were recorded, enumerated and isolated for further study. Isolates were identified using established methods, including aerotolerance testing, Gram staining, biochemical tests and enzyme profiling.\(^{18, 19}\) The species and clonal identity of selected \textit{Lactobacillus} GG isolates were confirmed by an arbitrarily primed-PCR (AP-PCR) method.\(^{20}\)

Faecal bile acid composition

Faecal bile acids were determined from a single stool sample by gas–liquid chromatography (HP 5890 series II, Hewlett-Packard, Wilmington, DE, USA) using a capillary column (HP-1, cross-linked methyl siloxane; length, 50 m; diameter, 0.32 mm; Hewlett-Packard, Wilmington, DE, USA).\(^{21}\) Results are given as the composition of individual bile acids expressed as a percentage of the total bile acids and micrograms of bile acids per gram of faeces.

Values presented as number of patients or as means ± S.E.M.
Clinical and microbiological results

Table 2 shows the mean PDAI scores, faecal pH and bacterial counts in faecal and tissue biopsy samples obtained before and after treatment with *Lactobacillus* GG or placebo.

The baseline total PDAI score ranged from 5 to 13 in both study groups. One patient in the placebo group and two patients in the *Lactobacillus* GG group had baseline total PDAI scores below 7. Figure 1 shows the changes in total PDAI score for patients treated with *Lactobacillus* GG or placebo. No differences were found in the mean pre-treatment or post-treatment PDAI scores between the groups. Clinical response (reduction in PDAI score of $\geq 3$) occurred in one female patient. Her concentration of faecal *Lactobacillus* GG increased from 0 to 7 log 10 colony-forming units/g, and her PDAI score decreased from 7 to 3. After treatment, she felt subjectively better than before treatment.

No significant changes were seen in the concentrations of total anaerobic and aerobic bacteria in the faecal, pouch and afferent limb mucosal biopsy samples between the placebo and *Lactobacillus* GG groups before or after supplementation. There was a trend towards higher faecal concentrations of total lactobacilli (from $5.0 \pm 0.8$ to $6.9 \pm 0.5$, *P* = 0.08) and a higher prevalence of lactobacilli-positive cultures in the pouch and afferent limb mucosa in patients treated with *Lactobacillus* GG. The ratio of total lactobacilli to total anaerobes increased from $0.53 \pm 0.08$ to $0.81 \pm 0.1$ (*P* = 0.03) in the *Lactobacillus* GG group (Table 2). No differences were observed in the total anaerobes, aerobes or total lactobacilli in the pouch or afferent limb mucosal biopsy samples.

Colonization of the pouch with *Lactobacillus* GG

None of the study subjects was *Lactobacillus* GG culture-positive before administration. During *Lactobacillus* GG administration, four of the 10 study subjects became faecal culture-positive for *Lactobacillus* GG. The effect of *Lactobacillus* GG supplementation on the counts of faecal and tissue biopsy bacteria in patients with and without faecal recovery of *Lactobacillus* GG is presented in Table 3. The mean faecal concentration of *Lactobacillus* GG-colonized patients was $6.11 \text{ log}_{10}$ colony-forming units/g (range, $2.5–8.7 \text{ log}_{10}$ colony-forming units/g). They showed a trend towards a lower ratio of total

Data expressed as mean ± S.E.M. or as number of patients.

*P* values are vs. placebo and were determined by the Mann–Whitney *U*-test or Fisher’s exact test. *P* < 0.05 was considered to be significant.

* * Significant increase from baseline level (*P* = 0.03, Wilcoxon signed rank test).
Possible factors influencing the colonization of the pouch with *Lactobacillus* GG were studied by logistic regression analysis, including pre-treatment PDAI, number of stools/day, time after surgery, faecal total primary bile acid (cholic acid + chenodeoxycholic acid) concentration, faecal pH and the number of exacerbations of pouchitis after surgery. No single factor was found to predict colonization.

**DISCUSSION AND CONCLUSIONS**

*Lactobacillus* GG, when administered twice daily in gelatine capsules for 3 months, was recovered in only 40% of study subjects. However, the supplementation increased the ratio of faecal total lactobacilli to total faecal anaerobes significantly, thus changing the intestinal flora in the ileo-anal pouches.

In our trial, no previous antibiotic medication was allowed, and none of the subjects was examined during acute exacerbation of pouchitis. Thus, we assumed that the baseline microbial and morphological changes represented a stable and long-term condition in the pouches. Based on these criteria, the most severe cases of pouchitis were excluded from the study. The mean PDAI score was therefore relatively low, ranging from 5 to 13, before administration of the study preparations. However, if pouchitis is defined according to Sandborn

Data expressed as mean ± S.E.M. Bacterial count presented in log_{10} colony-forming units per gram of tissue. Mann–Whitney U-test, *P* < 0.05 was considered to be significant.
et al. as a PDAI score of ≥7 (range, 0–18),22 nine of the 10 patients in the placebo group and eight of the 10 patients in the Lactobacillus GG group had pouchitis. Apart from one patient who felt that her condition improved, no marked difference in clinical, endoscopic or histological findings was found between baseline and the results after Lactobacillus GG supplementation. Thus, as primary therapy, Lactobacillus GG was not efficacious for the clinical improvement of pouch inflammation.

To treat patients with refractory pouchitis, Gionchetti et al. used a very high probiotic bacteria concentration (300 billion viable bacteria per gram) consisting of four strains of lactobacilli, three of bifidobacteria and one of Streptococcus salivarius ssp. thermophilus (VSL #3, Yovis:Sigma-Tau, Pomezia, Italy).8 The 40 patients with chronic pouchitis who initially achieved remission after combination antibiotic therapy were randomized to receive placebo or VSL #3 (3 g twice daily) for 9 months. In the probiotic-fed group, the relapse rate was significantly lower (15%) than in the placebo group (100%) after 9 months. In VSL #3-treated patients, faecal concentrations of lactobacilli, bifidobacteria and Streptococcus salivarius increased significantly. The adhesion and colonization capacity of these strains on the ileal mucosa is unknown.

It is generally agreed that probiotic bacteria must be capable of survival and colonization of the intestinal tract before they can influence human health.23 The ability of Lactobacillus GG to survive in the intestinal canal12, 24 and to colonize the gastrointestinal tract13, 25 has been shown for both adults and children.26 In healthy intestines, the colonization is prolonged for about 1 week,25 but the colon of one patient with ulcerative colitis was not colonized by Lactobacillus GG.13 Our knowledge of the ability of Lactobacillus GG to colonize the human small bowel after colectomy is limited. In our trial, Lactobacillus GG was recovered in the faecal flora in 40% of cases, but was not found in mucosal biopsies. No single factor predicting survival was found in a logistic regression analysis. However, it is evident that the fast transit time, high stool frequency (mean of seven per day in our study), watery stool and changes in mucosal morphology (villous atrophy) may disturb the adherence and colonization of probiotic bacteria. As Lactobacillus GG is adherent to intestinal mucus, the bolus of bacteria ingested in capsules may be washed out, together with ileal secretions.

Pettersson et al., studying patients with an ileostomy, administered buttermilk and yoghurt (which contain viable lactobacilli) and pure cultures of L. bulgaricus or L. acidophilus.27 After feeding, they cultured the ileostomy effluent. Not even a transient increase in lactobacilli counts was found in the ileostomy contents in subjects receiving buttermilk, yoghurt and L. bulgaricus. Those receiving pure cultures of L. acidophilus, which is of human origin, showed transient increases in lactobacilli counts (1–3 logs) in the ileostomy effluent approximately 1.5 h after feeding, with a maximum at 3.5 h; at 4.5 h, however, over 99.5% of the administered organism had passed out of the small intestine. As a buffering material, milk protects bacteria. It is evident that higher doses of probiotics may be needed for their intestinal survival when administration is in a freeze-dried form.

The effects of probiotics can be direct, or indirect through the modulation of the endogenous flora or the immune system.28 The mechanisms of action of probiotic bacteria may be based on the modulation of cytokine expression, or on the induction of nitric oxide synthase and matrix metalloproteinase activity.29 Earlier studies have shown that Lactobacillus GG supplementation increases the faecal total lactobacilli anaerobic counts and bifidobacteria concentrations significantly.30, 31 Madsen et al. have shown, in interleukin-10 gene-deficient mice, that normalization of colonic lumen Lactobacillus sp. levels reduces colonic mucosal adherent and translocated bacteria and prevents colitis.12 In the present study, no significant changes were noted in the concentrations of total anaerobes and aerobes in the faecal, pouch or afferent limb mucosa compared with the originally normal baseline levels. However, a significant increase occurred in the ratio of total lactobacilli to total anaerobes.

In conclusion, our data show that oral bacteriotherapy with the single-strain probiotic bacterium Lactobacillus GG can change the microbial flora in ileo-anal pouches. This study did not measure the effect of probiotic therapy on the recurrence of pouchitis. However, as primary therapy, Lactobacillus GG was inefficient for the clinical improvement of pouch inflammation. We recommend more placebo-controlled trials of probiotic use for pouchitis treatment.
