A B S T R A C T

Background & aims: Elevated soluble HLA-DR (sHLA-DR) serum levels have been reported in HLA class II-associated inflammatory disorders. We have previously shown that the HLA class II allele HLA-DRB1*01 may predispose to acute coronary syndromes (ACS). To our knowledge, sHLA-DR serum levels have not been studied in ACS.

Methods: sHLA-DR serum levels were measured in 477 ACS patients as cases and 475 area- and sex-matched controls by sandwich enzyme-linked immunosorbent assay. Binary logistic regression and ordinal logistic regression analyses adjusted for clinical parameters were conducted to evaluate the associations of sHLA-DR levels.

Results: ACS patients had lower sHLA-DR serum levels compared to controls (OR = 0.837; 95% CI = 0.704–0.994; p = 0.043). After adjustment for smoking status, this association was no longer significant. This was explained by the notion that current smoking was inversely associated with sHLA-DR levels both in cases (OR = 0.592; 95% CI = 0.553–0.908; p = 0.016) and in controls (OR = 0.356; 95% CI = 0.226–0.563; p = 0.000010). A similar effect was not seen with other cardiovascular risk factors.

Conclusions: The results indicate, for the first time, that lower sHLA-DR levels are associated with smoking, but not with ACS. This is an important finding because previous studies of sHLA-DR have not accounted for the possible associations between smoking and sHLA-DR levels. Further studies are required to confirm these novel results and explore the mechanisms behind the observed associations.

1. Introduction

Human leukocyte antigen (HLA)-DR molecules are present on the cell surface of antigen-presenting cells and can trigger immune reactions by presenting antigens to CD4 positive T-lymphocytes. HLA-DR molecules are also found in a soluble form (sHLA-DR) in almost every human body fluid including saliva, sweat, tears, serum, synovial fluid and urine [1–3]. sHLA-DR correlates with the amount of expression of membrane bound HLA-DR, possibly reflecting the inflammatory status [4].

According to previous studies, sHLA-DR serum or plasma levels have been reported to be elevated in patients with inflammatory diseases such as acute phase of multiple sclerosis [5], rheumatoid arthritis [6] and autoimmune hepatitis [7]. In patients with rheumatoid arthritis, sHLA-DR serum levels also correlated with disease activity [8] and decreased after immunosuppressive therapy with cyclosporine A [9]. On the other hand, decreased sHLA-DR serum levels have been associated with end-stage heart disease [10] and severe sepsis [11], and in patients with melanoma, sHLA-DR serum levels declined as the cancer progressed [12].

Disorders showing increased sHLA-DR serum levels have mostly been reported to be HLA class II-associated inflammatory disorders. HLA-DR-positive lymphocytes have been associated with acute coronary syndrome (ACS) [13] and we have shown that the HLA class II allele HLA-DRB1*01 may predispose to ACS [14,15]. In this
study, we investigated the relationship between sHLA-DR serum levels, ACS and cardiovascular risk factors.

2. Materials and methods

2.1. Study subjects

We selected ACS patients from the COROGENE study cohort of 5000 patients undergoing coronary angiogram at the Helsinki University Hospital in Finland between June 2006 and March 2008 [16]. Inclusion criteria in the current study were i) ACS, ii) age under 55 years for men and under 65 years for women, iii) home address in the capital region in Finland, yielding 488 cases in total. After excluding the cases with missing serum samples, the group of cases consisted of 477 ACS patients.

475 study subjects from the FINRISK 2007 study cohort served as sex- and area-matched controls [17]. The controls had to be free of cardiovascular disease at baseline. Details of the study subject selection and baseline measurements are reported in the Supplementary data.

All the study subjects gave their signed informed consent. The study protocol conforms to the ethical guidelines of the 1975 Declaration of Helsinki and the Ethics Committee of the University of Helsinki approved the COROGENE study and the Coordinating Ethical Committee of the Helsinki and Uusimaa Hospital District approved the FINRISK study.

2.2. Quantification of soluble HLA-DR

We detected sHLA-DR serum levels by sandwich enzyme-linked immunosorbent assay (ELISA) method developed in-house, described in detail in the Supplementary data.

2.3. HLA-DRB1*01 analyses

HLA-DRB1*01 genotypes from cases and controls were analysed from genomic DNA by real-time quantitative polymerase chain reaction technique with sequence specific primers as previously described [18]. Genotyping was unsuccessful in 1 case sample and 3 control samples. HLA-DRB1*01 carrier status was considered positive with 1 or 2 allele copies of HLA-DRB1*01.

2.4. Analyses for other parameters

All laboratory parameters: C-reactive protein (CRP), total leukocyte count (TLC), total cholesterol (TC), high-density lipo-protein-cholesterol (HDL-C), low-density lipoprotein-cholesterol (LDL-C), triglycerides (TG) and troponin T (TnT) were defined according to the laboratory standards of HUSLAB (Helsinki University Hospital Laboratory).

2.5. Statistical analyses

All the statistical calculations were performed with SPSS 21.0 (SPSS Inc., Chicago, IL, USA). We considered results significant at two-tailed p < 0.05 not correcting for multiple comparisons. sHLA-DR levels in serum samples were analysed both as a continuous variable and as a categorical variable as described in detail below. sHLA-DR levels under the detection limit (<0.1 µg/ml) were considered as 0.05 µg/ml when analysing the continuous sHLA-DR variable. sHLA-DR levels and other continuous variables were not normally distributed by the Kolmogorov-Smirnov normality test and logarithmic transformation did not transform them as such, apart from LDL-C and TC levels in controls and HDL-C in cases and controls. All the continuous variables are expressed as mean ± standard deviation (SD) and categorical variables as count (percentage). We compared continuous variables with a Mann-Whitney U test, Kruskal-Wallis test and Jonckheere-Terpstra test for trend, which are independent of distributional assumptions. Correlations between clinical parameters and sHLA-DR levels were analysed by nonparametric Spearman’s rank-order correlation test.

Based on the visual inspection of the distribution of the continuous sHLA-DR-variable, we cathegorized sHLA-DR levels into four groups: (I) under the detection limit of 0.100 µg/ml, (II) 0.100–0.300 µg/ml, (III) 0.301–2.000 µg/ml and (IV) over 2.000 µg/ml to obtain a categorical variable of sHLA-DR levels. A Chi-square test, a Mantel-Haenszel Linear-by-Linear Association test for trends or Fisher’s exact test was used to determine associations between categorical variables. We compared cases and controls regarding logarithmically transformed sHLA-DR levels in binary logistic regression models, firstly adjusted for age and sex, secondly adjusted for age, sex and smoking status, thirdly in a multivariable-adjusted model (adjusted for sex and parameters differing between cases and controls: age, body mass index [BMI], smoking status, diabetes, asthma, cancer and CRP), and finally in a multivariable-adjusted model without smoking status.

We performed ordinal logistic regression models adjusted for age and sex using categorical sHLA-DR as a dependent variable, and BMI, smoking status (current versus never-smoking), diabetes, HLA-DRB1*01, asthma, cancer, rheumatoid arthritis or CRP as explanatory variables, first separately and then together in the same model, to assess the influences of different cardiovascular risk factors on the sHLA-DR levels, determining OR and 95% confidence intervals (95% CIs) for ordinal logistic regression models. This OR for a specific explanatory variable measures the odds of being in a group of a higher sHLA-DR level (higher group defined as any of the three separate ways: group IV vs. groups I-III, groups III and IV vs. I and I and II and groups II-IV vs. group I) compared to the groups of lower sHLA-DR level. Proportional odds of ordinal regression analyses met the criteria for p > 0.050.

3. Results

3.1. Baseline characteristics

Baseline characteristics are shown in Table 1. As expected, the cases had more cardiovascular risk factors and cardiovascular medications. Among cases, the distribution of different ACS types was the following: unstable angina 8.2% (n = 39), ST elevation myocardial infarction 47.6% (n = 227) and non–ST elevation myocardial infarction 44.2% (n = 211).

3.2. sHLA-DR levels

Table 2 presents the sHLA-DR serum levels in the study subjects. Cases had significantly lower levels of sHLA-DR (mean 1.71 ± 9.53 µg/ml) than controls (mean 2.83 ± 17.11 µg/ml; p = 0.032). The linear trend was borderline insignificant (p = 0.050), showing lower sHLA-DR levels in cases than controls. However, sHLA-DR levels over the 95th percentile (>6.67 µg/ml) of the control group were found with a similar frequency in cases (n = 23, 4.8%).

In the binary logistic regression analysis adjusted for age and sex, the logarithmically transformed sHLA-DR level associated inversely with ACS (OR = 0.811; 95% CI = 0.681–0.966, p = 0.019). In the multivariable-adjusted binary logistic regression, the association was no longer significant (OR = 0.938; 95% CI = 0.764–1.152, p = 0.497), indicating that differences in sHLA-DR levels between cases and controls were not explained by disease status, but by other factors differing between cases and controls (Table 3). We
found that the presence of smoking status changed the significance of the models, adjustment for smoking status reduced the association between sHLA-DR levels and ACS (Table 3). However, the interaction term between smoking status and logistically transformed sHLA-DR level was insignificant in relation to ACS patient status, in the binary logistic regression model using ACS patient status as a dependent variable, and logistically transformed sHLA-DR level, smoking status and interaction term between smoking status and logistically transformed sHLA-DR level as explanatory variables.

### 3.3. sHLA-DR levels and cardiovascular risk factors

Next, we sought to assess the correlation of sHLA-DR and cardiovascular risk factors. In both cases and controls, sHLA-DR levels correlated inversely with current smoking (ρ = -0.112, p = 0.026 and ρ = - 0.241, p < 0.0001, respectively). In cases, no other correlations were found, whereas in controls sHLA-DR levels also correlated inversely with age (ρ = -0.111, p = 0.016) and HLA-DRB1*01 positivity (ρ = -0.110, p = 0.017). The only factor with a significant positive correlation with sHLA-DR was the history of rheumatoid arthritis in controls (ρ = 0.153, p = 0.001). The Spearman’s rank-order correlations between sHLA-DR levels and different variables are summarized in Supplementary Table 1.

When the different sHLA-DR groups (I-IV) were compared against the risk factors, current smoking showed a significant linear trend with decreasing sHLA-DR levels in both cases and controls and rheumatoid arthritis showed a linear trend with increasing sHLA-DR levels in controls (Supplementary Table 2A and B).

We assessed the associations between groups of sHLA-DR level with cardiovascular risk factors by ordinal logistic regression analysis adjusted for age and sex. The results showed that current smoking was inversely associated with sHLA-DR levels in cases and controls (OR = 0.595; 95% CI = 0.553–0.608; p = 0.016 and OR = 0.356; 95% CI = 0.226–0.563; p = 0.000010). In addition, HLA-DRB1*01 positivity was inversely and rheumatoid arthritis directly associated with sHLA-DR levels in controls (OR = 0.595; 95% CI = 0.401–0.882; p = 0.010 and OR = 5.865; 95% CI = 2.042–16.861; p = 0.001). Multivariable ordinal logistic regression model adjusted for age and sex, including BMI, smoking status (current versus never-smoking), diabetes, HLA-DRB1*01, asthma, cancer, rheumatoid arthritis and CRP as explanatory variables, did not change these results.

Number of cigarettes smoked per day and duration of smoking cessation data were available only for controls and these data were not associated with sHLA-DR levels. Table 4 summarizes the differences in clinical variables between current smokers and never-smokers among cases and controls.

### 4. Discussion

In this study, we discovered a previously unreported association between smoking and lower sHLA-DR levels. This association was confounding our preliminary observation, which showed that ACS patients had lower sHLA-DR levels than controls. As the case population included more smokers than the control population, after correcting for smoking status, no association between sHLA-DR levels and ACS patient status could be seen. This finding raises the question whether possible associations between smoking and sHLA-DR levels should always be considered when analysing sHLA-DR levels.

DR levels, especially in diseases known to be associated with smoking, and when the frequency of smokers differs between the study groups.

4.1. sHLA-DR and smoking

Cigarette smoking has both pro-inflammatory and immune suppressive influences on the immune system [19]. Smoking increases the risk of various autoimmune diseases with mechanisms which are still poorly understood [20,21]. It is a strong environmental risk factor for coronary artery disease as well as for rheumatoid arthritis [22,23].

To our knowledge, the previous studies of sHLA-DR have not assessed the associations between smoking and sHLA-DR levels. Interestingly, alveolar macrophages of smokers have been observed to express less HLA-DR compared to alveolar macrophages of non-smokers [24,25]. As the surface expression of HLA-DR has been shown to correlate with sHLA-DR [4], this could corroborate our findings. As our material seems to be nearly three times larger than any of the previous studies of sHLA-DR, the previous studies may also have been underpowered to detect such an association [18,34].

It is important to note that smoking explained only part of the variation in sHLA-DR levels and the strength of the correlation was modest. However, in cases, no other factor was identified with a significant correlation with sHLA-DR. In the control population, age, rheumatoid arthritis and HLA-DRB1*01 carrier status were all associated with sHLA-DR. Even though the amount of smoking per
4.4. Conclusions

Described the methods we used and explained the motives we had for the associations as insignificant of smoking in cases, which could have affected the results. We did not find an association between ACS and sHLA-DR. However, we were able to confirm the previously reported association of rheumatoid arthritis with higher sHLA-DR levels in our control population [8]. Other markers of inflammation or CRP were not associated with sHLA-DR levels. In controls, increasing age usually associated with increased levels of inflammation, exhibited inverse correlation with sHLA-DR.

In a previous study, sHLA-DR serum levels were higher in rheumatoid arthritis patients with disease-associated epitope, including HLA-DRB1*01 and HLA-DRB1*04 alleles, compared to rheumatoid arthritis patients without this disease-associated epitope [8]. In the present study, HLA-DRB1*01 negative controls had higher serum levels of sHLA-DR than HLA-DRB1*01 positive controls. By contrast, we did not observe any correlation between HLA-DRB1*01 allele positivity and sHLA-DR serum levels in cases. On the other hand, HLA-DRB1*01 negative cases were current smokers with a significantly higher frequency compared to HLA-DRB1*01 positive cases, which might have affected the results.

We detected sHLA-DR levels ≥0.100 μg/ml and nearly half of our cases and controls had detectable levels of sHLA-DR in serum. By contrast in former studies the percentage of control subjects showing detectable levels of sHLA-DR in serum has ranged from 8 to 100%. This is probably due to different quantification methods which complicates the comparison of sHLA-DR levels between different studies. Given the lack of established methods for sHLA-DR measurement, we performed validations to confirm our method.

4.2. sHLA-DR and inflammation

Previous, smaller studies (ranging from 5 to 386 study subjects) have shown that sHLA-DR serum or plasma levels are elevated in patients with HLA class II-associated inflammatory disorders. Even though the HLA-DRB1*01 was associated with ACS in the present, largest study of sHLA-DR (958 study subjects), we could not find an association between ACS and sHLA-DR. However, we were able to confirm the previously reported association of rheumatoid arthritis with higher sHLA-DR levels in our control population [8]. Other markers of inflammation or CRP were not associated with sHLA-DR levels. In controls, increasing age usually associated with increased levels of inflammation, exhibited inverse correlation with sHLA-DR.

In a previous study, sHLA-DR serum levels were higher in rheumatoid arthritis patients with disease-associated epitope, including HLA-DRB1*01 and HLA-DRB1*04 alleles, compared to rheumatoid arthritis patients without this disease-associated epitope [8]. In the present study, HLA-DRB1*01 negative controls had higher serum levels of sHLA-DR than HLA-DRB1*01 positive controls. By contrast, we did not observe any correlation between HLA-DRB1*01 allele positivity and sHLA-DR serum levels in cases. On the other hand, HLA-DRB1*01 negative cases were current smokers with a significantly higher frequency compared to HLA-DRB1*01 positive cases, which might have affected the results.

We detected sHLA-DR levels ≥0.100 μg/ml and nearly half of our cases and controls had detectable levels of sHLA-DR in serum. By contrast in former studies the percentage of control subjects showing detectable levels of sHLA-DR in serum has ranged from 8 to 100%. This is probably due to different quantification methods which complicates the comparison of sHLA-DR levels between different studies. Given the lack of established methods for sHLA-DR measurement, we performed validations to confirm our method.

4.3. Limitations

Our study has some limitations that should be considered. We were able to obtain only one serum sample from each study subject. Thus, we did not know whether the detected sHLA-DR level was the case’s constant state or, for example, a temporary consequence of a case’s constant state or, for example, a temporary consequence of smoking. We did not have information of amount and duration of smoking in cases, which could have affected the results. We did not use statistical adjustments for multiple testing because we wanted to avoid to increase the probability of considering truly important associations as insignificant. We rather carefully described the methods we used and explained the motives we had behind the different analyses.

4.4. Conclusions

The results indicate for the first time that lower sHLA-DR levels are associated with smoking, but not independently associated with ACS. This is an important finding because the previous studies of sHLA-DR have not accounted for the possible associations between smoking and sHLA-DR levels. Further studies are required to confirm these novel results and explore the mechanisms behind the observed associations.

Conflict of interest

The authors declared they do not have anything to disclose regarding conflict of interest with respect to this manuscript.

Financial support

This study was financially supported by Ida Montin Foundation, Emil Aaltonen Foundation, Aranne Koskelo Foundation, Finnish Medical Foundation and Finnish Foundation for Cardiovascular research, and Helsinki University Central Hospital special government funds (EVO #TYH2012209, #TYH2014312, #TYH2017250).

Author contribution

J.T. set up the research method (sandwich ELISA), performed statistical analyses and drafted the manuscript. R.T. took part in research protocol design and helped with statistical analyses and drafting the manuscript. H.J helped to set up the ELISA method and perform the data analyses. P.P helped with building up the ELISA method, V.S and A.H participated in data collection. M-LL and J.S participated in research protocol design and data collection and supervised the whole study project. All authors critically revised the manuscript, read and approved the final manuscript.

Acknowledgements

The authors thank Seppo Meri for providing laboratory facilities and Lauri Snellman for participating in laboratory analyses.
