16 **Abstract**

17 The worldwide use of ionic liquids (ILs) is steadily increasing, and even though they are often referred
18 to as “green solvents” they have been reported to be toxic, especially towards aquatic organisms. In this
19 work, we thoroughly study two phosphonium ILs; octyltributylphosphonium chloride ([P₈₄₄₄]Cl) and
20 tributyl(tetradecyl)phosphonium chloride ([P₁₄₄₄₄]Cl). Firstly, the critical micelle concentrations (CMCs)
21 of the ILs were determined with fluorescence spectroscopy and the optical pendant drop method in order
22 to gain an understanding of the aggregation behavior of the ILs. Secondly, a biomimicking system of
23 negatively charged unilamellar liposomes was used in order to study the effect of the ILs on
24 biomembranes. Changes in the mechanical properties of adsorbed liposomes were determined by quartz
25 crystal microbalance (QCM) measurements with silica coated quartz crystal sensors featuring a
26 polycation layer. The results confirmed that both ILs were able to incorporate and alter the biomembrane
27 structure. The membrane disrupting effect was emphasized with an increasing concentration and alkyl
28 chain length of the ILs. In the extreme case, the phospholipid membrane integrity was completely
29 compromised.

1. Introduction

Ionic liquids (ILs) are salts which typically are in melted state at temperatures below 100 °C. Their main benefits are a negligible vapor pressure, an ability to dissolve a large number of compounds, and the possibility to design on-demand ILs by combining different cations and anions [1]. Due to their low vapor pressures, ILs have often been referred to as “green solvents” because this enables an easier handling and storage of ILs [2]. Many recent studies, however, suggest that ILs possess a considerable toxicity, especially in aquatic environments [1, 3, 4]. ILs are frequently used in a large number of applications, yet there is still a considerable lack of information about their interaction with living organisms. Therefore, further characterization of ILs in this regard is of paramount importance.

Phosphonium-based ILs are a class of compounds where the phosphorus atom in the cation is typically bound to four alkyl substituents. In this work we investigate lipid membrane interactions with two commercially available phosphonium chloride ILs with long alkyl chains, namely octyltributylphosphonium chloride ([P₈₄₄₄]⁺Cl⁻) and tributyl(tetradecyl)phosphonium chloride [P₁₄₄₄₄]⁺Cl⁻ (Figure 1). Recent applications include the use of phosphonium ILs for nucleation and electrodeposition of metals [5, 6], for analyte separations in analytical chemistry [7, 8], in liquid-liquid extractions [9, 10], and for selective capture and detection of arsenic [11]. Because cations of the ILs used in this study are amphiphilic we first evaluated whether these form micelles. The critical micelle concentration (CMC) is a very important characteristic of an amphiphilic compound. The CMC is reflected as a sudden change in solution properties when micelles are formed [12]. The formation of micelles may affect the way the compounds interact with biomembranes. There are several methods for CMC determination, such as conductivity, NMR diffusion, surface tension, fluorescence spectroscopy, and others (see reference [13]). CMC values in this study were determined with fluorescence spectroscopy and surface tension analysis.

59 The biomembrane is one of the key cellular structures, which protects a cell from the external
60 environment. Thus, any alteration or disruption of the biomembrane can have serious or even lethal
61 consequences for the organism. It has recently been reported that imidazolium based ILs can induce
62 membrane fusion [14] and alter membrane permeability [15]. Much in the same way as certain
63 amphipathic α -helical peptides, positively charged surfactants, and other peptides [16-21]. Therefore,
64 further knowledge about the behavior of phosphonium ILs in regard to their interactions with
65 biomembranes can bring light onto possible benignity or toxicity of particular ILs.

66
67 Coating of surfaces with phospholipids is often a method of choice for studying interactions between
68 model biomembranes and various compounds [22, 23]. Furthermore, it is possible to obtain a deeper
69 understanding about the mechanism of how compounds influence the membrane structure by observing
70 changes in the properties of phospholipid layers adsorbed on solid surfaces [19, 24]. Advanced quartz
71 crystal microbalance techniques (QCM), i.e. impedance based QCM or QCM with dissipation
72 monitoring, are powerful tools for determining various properties (e.g. thickness, mass, and
73 viscoelasticity) and interaction dynamics of adsorbed layers. One of the main advantages of advanced
74 QCM techniques is that they enable fast and label-free detection of compounds interacting with the sensor
75 [25]. The resonance frequency of a quartz crystal sensor is dependent on the mass of the adsorbed layer,
76 whereas the change in energy dissipation of the sensor (ΔD) provides information about viscoelastic
77 properties of the adsorbed layer. In this regard, advanced QCM can be considered as a biosensing device
78 where the resonance frequency and energy dissipation of the sensor with a bound biological structure (e.
79 g. lipid bilayer/liposomes) will change upon addition of ILs interacting with the system [25, 26].
80 Advanced QCM can also provide highly relevant information about disruption of lipid bilayers [27],
81 interaction with membrane active moieties [28], binding dynamics [26], and lipid packing density [29].

82 Zwitterionic and anionic phospholipids are the most abundant components of biomembranes. In this
83 work, zwitterionic egg L- α -phosphatidylcholine (eggPC) and negatively charged 1-palmitoyl-2-oleyl-*sn*-
84 glycerol-3-[phospho-*rac*-(1-glycerol)] (POPG) were used for preparation of liposomes. These liposomes
85 were used in the form of large unilamellar vesicles with approximate diameters of 130 nm. Such a system
86 was used in our previous study, where interactions between liposomes and ILs were investigated with
87 capillary electromigration techniques [30]. In order to better understand the interactions observed in our
88 previous study, this work focused on the characterization of ILs and their influence on liposomes. It has
89 already been shown that liposomes bind to silica surface, and based on their composition, size,
90 concentration, and experimental conditions they can either adsorb as intact liposomes or rupture to form
91 phospholipid bilayers on the silica surface [21, 31, 32]. Increase in porosity of such silica surfaces has
92 also been reported to increase the kinetics of vesicle rupture and bilayer formation [33]. The liposomes
93 used in our study were highly negatively charged due to 25 mol% of anionic POPG. Since the silica
94 surface of the QCM sensor was negatively charged at the used pH of 7.4 (the pK_a value of the silanol
95 groups is approximately 4.9, meaning almost complete dissociation), it was necessary to apply a fast and
96 reliable coating method with cationic layer. This prevented unwanted interactions with the cationic ILs,
97 which would eventually result in the formation of a 'dynamic' IL coating. Furthermore, it ensured fast
98 liposome binding to the sensor surface. Positively charged polyelectrolyte coatings can be utilized to
99 screen off the surface interactions between positively charged compounds and the negatively charged
100 silanols [34]. Polybrene, a widely used cationic polyelectrolyte for coating of silica [35], was employed
101 in this work. The same polyelectrolyte was also utilized in our recent capillary electrophoresis study of
102 interactions between the same liposome-ILs systems with common pharmaceuticals [30]. In this work, we
103 will demonstrate that QCM is a highly suitable technique for analysis of interactions between
104 phosphonium ILs and phospholipid membranes, providing new insight into the possible mechanism of

105 ILs toxicity. Moreover, the QCM methodology will also be used to bring complimentary information on
106 trends and phenomenon observed in our previous study [30].

107

108 **2. Materials and methods**

109 *2.1 Chemicals*

110 POPG (sodium salt) was purchased from Genzyme Pharmaceuticals (Liestal, Switzerland), EggPC (Egg,
111 Chicken) was purchased from Avanti Polar Lipids (Alabaster, AL, USA). Polybrene (hexadimethrine
112 bromide) was purchased from Fluka (Buchs, Switzerland). Hydrogen sodium phosphate, hydrogen
113 peroxide (H₂O₂; 50% weight in H₂O), ammonium hydroxide (NH₄OH; 30% weight in H₂O), and 3-[(3-
114 cholamidopropyl)dimethylammonio]-1-propanesulphonate (CHAPS) (purity of 98%) were purchased
115 from Sigma (Darmstadt, Germany). Dihydrogen sodium phosphate monohydrate and HPLC-grade
116 methanol were from Mallinckrodt Baker (Deventer, The Netherlands). The pH calibration solutions (7.01
117 and 10.01) were purchased from Merck (Darmstadt, Germany). Sodium hydroxide (1.0 M) was from FF-
118 Chemicals (Yli-Ii, Finland) and chloroform from Rathburn (Walkerburn, UK). Distilled water was
119 further purified with a Millipore water-purification system (Millipore, Molsheim, France). Sodium
120 dodecyl sulfate (SDS, purity of 99%) and pyrene (GC-grade; purity of 99%) were obtained from Merck
121 (Darmstadt, Germany) and Fluka (Sigma-Aldrich, Switzerland), respectively. 1-Ethyl-3-
122 methylimidazolium acetate [emim][OAc] was purchased from Iolitec GmbH (Heilbronn, Germany).
123 [P₈₄₄₄]⁺Cl⁻ and [P₁₄₄₄₄]⁺Cl⁻ were provided by Cytec Industries (Woodland Park, NJ, USA).

124

125 2.2 Buffer preparation

126 Sodium phosphate buffer was prepared by mixing disodium hydrogen phosphate and sodium dihydrogen
127 phosphate to yield an ionic strength of 10 mM and a pH of 7.4. The buffer solution was filtered through
128 a 0.45- μ m polytetrafluoroethylene syringe filter (Gelman Sciences, Ann Arbor, MI, USA) before use.
129 Sodium phosphate buffer was used as a solvent for liposomes and ILs preparation and as a solvent in all
130 QCM and CMC measurements.

131

132 2.3 Liposome preparation

133 A 3.0 mM dispersion of liposomes was prepared by mixing appropriate volumes of stock solutions of
134 eggPC (20 mM) and POPG (15 mM) in chloroform. The mixing ratio of lipid stock solutions in
135 chloroform was 75/25 molar percentage of eggPC/POPG. The resulting mixture was dried under a stream
136 of pressurized air and chloroform residues were removed by overnight evacuation in an exicator. The
137 phospholipids were hydrated in the sodium phosphate buffer for 60 min at 60°C and shaken continuously
138 to yield multilamellar vesicles. The resulting dispersion was processed to large unilamellar vesicles by
139 19 times extrusion through 100-nm pore sized polycarbonate filters (Millipore, Bedford, MA, USA) with
140 a Liposo-Fast extruder (AVESTIN, Ottawa, ON, Canada). Liposome sizes of approximately 130 nm
141 were routinely confirmed by Malvern Zeta Sizer (Malvern, Great Britain).

142

143 2.4 Fluorescence spectroscopy

144 The fluorescence spectroscopy measurements were performed at room temperature with a FluoroMax4
145 Spectrofluorometer (Horiba Jobin Yvon, Edison, NJ, USA). Fluorescence emission spectra of IL or SDS
146 solutions, containing 0.1 μ M of pyrene, were measured at 391 nm using a 1 cm quartz cuvette. The SDS
147 measurements were performed to confirm that the system was working appropriately. The aggregation
148 of surfactants, using pyrene as a fluorescence probe, was evaluated from the emission spectra by

149 determining the intensity ratios of the first and third vibronic peak (I_1/I_3) located near 370 and 380 nm,
150 respectively. Excitation and emission slits were set at 5 nm and 1 nm, respectively. The collection and
151 evaluation of data was performed with the FluorEssence software (Horiba Scientific, Edison, NJ, USA).
152 All fluorescence measurements were repeated three times. The relative standard deviation of sequential
153 measurements of the pyrene 1:3 ratio did not exceed 1%.

154

155 A 1 μ M pyrene stock solution was prepared by dissolving pyrene in water, followed by bath sonication
156 for 30 min. The pyrene water solution was oscillated at room temperature in the dark overnight in order
157 to get a saturated stock solution. 50 mM SDS stock solution and 10 mM IL stock solutions were prepared
158 by dissolving an appropriate amount of surfactant in water or sodium phosphate buffer. Diluted solutions
159 were shaken for 15 min and sonicated for another 15 min. Solutions were protected from light and stored
160 at 4 °C. Dilution series for fluorescence measurements were prepared by mixing appropriate amounts of
161 surfactants in a saturated pyrene solution to get concentrations between 0.1–3.0 mM. Prior to any analysis
162 the prepared solutions were shaken and sonicated for 15 min in the dark. All CMC analyses were done
163 at 25 °C.

164

165 The CMC value (x_{CMC}) was derived according to the method by Aguiar *et al.* [36]. The Boltzmann
166 sigmoid function (equation 1) was fitted to a pyrene 1:3 ratio versus surfactant concentration plot with
167 ORIGIN 8.0 (OriginLab, MA, USA) to extract the parameters x_0 (i.e. the sigmoid center) and Δx (i.e.
168 range in which the pyrene 1:3 ratio drop occurs). The CMC values were then determined by using
169 equation 2 and the extracted x_0 and Δx parameters.

170

171
$$y = \frac{A_2 - A_1}{1 + e^{\frac{x - x_0}{\Delta x}}} + A_2 \quad (1)$$

172

173 In Equation 1 the parameters A1 and A2 are the higher and lower limits of the sigmoid, respectively.

174

175
$$x_{CMC} = x_0 - 2 \cdot \Delta x \quad (2)$$

176

177 *2.5 Optical pendant drop method*

178 The surface tension measurements were performed with the pendant drop method at room temperature
179 with a CAM 200 Optical Contact Angle Meter (Biolin Scientific, Attension, Finland) equipped with a
180 CCD Video Camera Module. Measurements were performed by collecting 20 frames at a frame interval
181 of 1 s. Evaluation of the data was performed with the Attension Theta Software (ver. 4.1.0, Biolin
182 Scientific, Finland). Fitting of collected images was done with the Young-Laplace equation. ILs were
183 diluted in MilliQ water and sodium phosphate buffer and each sample was measured three times.

184

185 *2.6 Quartz crystal microbalance*

186 Interactions between additives and silica were performed with an impedance-based quartz crystal
187 microbalance technique (QCM-Z500; KSV, Biolin Scientific, Finland). Individual experiments were
188 performed by using a constant liquid flow of 300 $\mu\text{L min}^{-1}$ through the QCM flow channel thermostated
189 at 20 °C. Before use, the silica coated quartz crystal sensors were conditioned by using the following
190 procedure. The quartz crystal sensor was first immersed for 5 min into a boiling solution of
191 $\text{NH}_4\text{OH}/\text{H}_2\text{O}_2/\text{H}_2\text{O}$ (1/1/5 v/v/v). Hereafter, the quartz crystal sensor was washed with water and dried
192 with air. After placing the quartz crystal sensor into the measuring chamber, a coating method consisting
193 of five subsequent 400 s washes of water, 0.1 M sodium hydroxide, water, 1% polybrene (in water) (m/v),
194 and water was applied. For polybrene-free measurements the chip was only washed with water, 0.1 M
195 sodium hydroxide, and water; each for 400 s. A sodium phosphate buffer wash was used at the start of

each analysis, followed by a 200 s wash with a 0.3 mM liposome dispersion. Subsequently 400 s washes with solutions of increasing IL concentrations were applied. After each complete measurement the silica coated quartz crystal sensor was cleaned *in situ* in the QCM flow channel by washing it with 20 mM CHAPS, 0.1 M sodium hydroxide, ethanol, and water. The QCM flow channel was filled with water between the analyses.

Resonance parameters were measured at the fundamental frequency of around 5 MHz and at four overtones ($n = 3, 5, 7$, and 9 , corresponding to frequencies close to 15, 25, 35, and 45 MHz). The data obtained from the QCM measurements were analyzed with the QCM-Z500 data analysis software suite, version 3.30, and the adsorbed layer thickness along with the viscoelastic properties were determined by using a Voigt viscoelastic representation of the adlayer as described by Bandley et al. [37]. The following starting parameters were used for fitting the viscoelastic film properties: film thickness of $0.01\ \mu\text{m}$, film elasticity of $0.1\ \text{MPa}$, and film viscosity of $0.001\ \text{Pa}\cdot\text{s}^{-1}$. The density of the surrounding liquid and the density of the formed liposome layer or lipid bilayer were kept constant at $0.9986\ \text{g}\cdot\text{cm}^{-3}$ and $1.06\ \text{g}\cdot\text{cm}^{-3}$ [38, 39]. Relaxation times were finally obtained by dividing the calculated layer viscosity by the calculated layer elasticity.

3. Results and discussion

The aim of the work was to gain further insight into how ILs interact with liposomes. First, the CMCs values of the studied ILs were determined in order to evaluate their surfactant properties. Second, QCM was applied to obtain information on the change of mechanical properties of liposomes when exposed to surface active compounds. Moreover, a silica coating adsorption study of a positively charged polyelectrolyte layer was also done with QCM. This system was recently utilized in one of our capillary electrophoresis studies [30]. The results obtained from polyelectrolyte layer – liposome – ILs interaction

studies would therefore also help to gain a better understanding on the behavior of polyelectrolyte modified fused silica systems used in capillary electrophoresis.

3.1 Determination of CMC of ILs

In our recent study, we have observed that the ILs used in this work suppress the electroosmotic flow (EOF) in fused silica capillaries [30]. In this work, the CMCs were determined in order to investigate if the suppression of the EOF by these ILs was related to their self-aggregation. The aggregation of ILs might also influence their interactions with liposomes; hence, CMC values of the phosphonium ILs in water and in phosphate buffer were determined using fluorescence spectroscopy and surface tension analysis.

In the fluorescence spectroscopy approach, the CMC values were determined by using a pyrene 1:3 ratio method [40], where solvent dependent fluorescence emissions of pyrene were determined. The characteristic emission spectra of pyrene, shown in Figure 3B, have five maxima in the range 360–400 nm (Figure 3B). The first (I_1) and third (I_3) vibronic bands of the pyrene emission spectrum are located at 370 and 380 nm, respectively, and their intensities are highly dependent on the polarity of the environment of the pyrene probe. Below the CMC the 1:3 pyrene ratio is dependent on the polarity of the solution, while above the CMC it decreases rapidly because the probe transfers to the more hydrophobic environment inside the aggregated surfactants [40].

As a comparison, CMC values were also determined with the optical pendant drop method. When the concentration of a surface-active compound increases, the monomers orientate at the surface of the drop in order to decrease the free energy of the system until the surface is fully covered. The surface tension of the drop, therefore, decreases until the CMC is reached. Hereafter, the surface tension levels out and

reaches an almost constant value due to the aggregation of any further monomers introduced to the system [41]. The surface tension values were derived by fitting the Young-Laplace equation to drop shapes of solutions with increasing IL concentration. The CMC value was then derived from the intersection point of two trend lines when the surface tension was plotted against an increasing concentration of the corresponding IL.

The plot of surface tension versus concentration of [P₈₄₄₄]Cl is shown in Figure 2. The CMC values of [P₈₄₄₄]Cl in either water or phosphate buffer could not be determined due to the lack of a clear breakpoint in the surface tension-concentration curve. The surface tension of the [P₈₄₄₄]Cl solutions decreased without reaching a constant value, indicating that additional monomers were assembling at the surface of the drop rather than forming full-size micelles. The decrease was, however, not linear, which indicates that [P₈₄₄₄]Cl monomers aggregate to form oligomers but no micelles in a similar way as has previously been shown for other surfactant systems [42, 43]. In addition, the steepest change in the surface tension occurred in the concentration range from 5 to 10 mM, which can be taken as an indication of the onset of aggregation. In contrast to phosphonium ILs, aggregation of imidazolium based ILs has been investigated by several research groups [44]. Blesic *et al.* have suggested that imidazolium cations possessing at least eight carbons, with chlorine anions, can form micelles [45]. Chen *et al.* have shown that close-to-spherical charged micelles can already be formed when the alkyl chain contains more than four carbons [46]. These findings are in contradiction with the behavior observed for [P₈₄₄₄]Cl. We speculate that the bulky headgroup of [P₈₄₄₄]Cl which contains three butyl chains makes a sterical obstacle for a neat arrangement and further aggregation of the molecules, thus preventing micelle formation in this case.

267 The CMC values of [P₁₄₄₄₄]Cl determined by fluorescence spectroscopy were 0.90 mM in water and 0.60
268 mM in the phosphate buffer, respectively. The corresponding values measured using the optical pendant
269 drop method were 0.92 mM and 0.54 mM, respectively (Figure 3). The lower CMC value of [P₁₄₄₄₄]Cl
270 in phosphate buffer compared to water originates from the fact that an increased concentration of ions in
271 the buffer system stabilizes the aggregates by reducing the repulsion between polar head groups leading
272 to a decrease in the CMC value [47, 48]. The results of both techniques correlate very well with each
273 other, which indicates that both techniques are suitable for CMC determinations of the ILs used in this
274 work.

275

276 3.2 Quartz crystal microbalance

277 QCM experiments were performed to find out how liposomes used as model cell biomembranes interact
278 with ILs. The QCM method appears to be an excellent choice for such measurements as it can measure
279 not only a change in adsorbed mass but it can also provide an estimate of the thickness and mechanical
280 properties of an adsorbed layer. Motivation to this work was based on findings from our recent liposome
281 electrokinetic chromatography study [30]. There, we observed that eggPC/POPG liposomes did not at
282 all adsorb on bare silica capillaries, whereas they were readily adsorbed on polybrene coated fused silica
283 capillary walls, consequently resulting in a doubly reversed electroosmotic flow. Hence, a silica coated
284 sensor with and without adsorbed polybrene was used in this study to obtain a deeper understanding of
285 the system previously used for electrokinetic chromatography studies.

286

287 As noticed in our previous study on fused silica capillaries [30], neither in this work did we observe any
288 adsorption of negatively charged eggPC/POPG liposomes onto the bare silica coated sensor (Figure S1).
289 This is in contrast with available literature where negatively charged liposomes have been shown to
290 adhere to the silica surface of a QCM sensor [49, 50]. Furthermore, the adsorption behavior of different

291 compositions of liposomes in connection to the formation of supported lipid bilayers (SLB) on silica and
292 other polar surfaces such as glass, quartz, titania, mica, etc. has been thoroughly investigated by QCM
293 and related techniques [21, 32, 50, 51]. For example, positively charged liposomes (i.e. DOTAP) were
294 shown to readily adhere to a negatively charged silica surface and instantly form an SLB, while a highly
295 negatively charged liposome (i.e. DOPC/DOPS, 1:2 molar ratio) did not adsorb at all on silica [32]. The
296 adsorption of negatively charged DOPC/DOPS liposomes on the silica surface was not observed until
297 the ratio of the negatively charged lipid (i.e. DOPS) to the zwitterion lipid (i.e. DOPC) exceeded 1:1. It
298 was shown that POPC/POPS extruded liposomes with a molar ratio of 1:1 have a zeta potential of about
299 -38.4 mV [52]. EggPC/POPG 3:1 liposomes used in our study featured a zeta potential of -80 mV [53].
300 Based on these studies, we can conclude that the lack of adsorption of EggPC/POPG liposomes (molar
301 ratio 3:1) on silica observed in this work was caused partly by the highly negative nature of the used
302 liposomes and partly because of the 10 min 0.1 M NaOH pre-treatment process of the silica sensor. The
303 pre-treatment of the silica sensors with NaOH simulates the pre-treatment process used for silica
304 capillaries in our previous electrophoresis study [30]. Concentrated NaOH causes etching of the silica
305 surface potentially producing a higher number of vicinal silanol groups, which dissociates at neutral pH
306 [54]. However, it is also important to take into account a hysteresis effect when considering the silica
307 surface charge. It can take from minutes to hours until the system is fully stable after treating it with
308 NaOH [55]. Both NaOH effects increase the overall silica surface charge of the sensor, which would
309 consequently result in an increased repulsion between the highly negatively charged liposomes and the
310 silica surface.

311

312 The polybrene coating process of the silica surface was optimized in our previous capillary
313 electrophoresis study [30]. In this work, the same coating procedure was utilized before each QCM
314 experiment. A 0.1 M NaOH wash was used to deprotonate the silanol groups and to enhance the

adsorption of polybrene. During the optimization, it was found that a 1% (m/v) concentration of polybrene in water coated the silica sensor with a polybrene layer of a thickness of ~1 nm. This correlates well with the thickness of a polybrene layer on silica recently determined by atomic force microscopy [56]. After the silica sensor was coated with polybrene, the EggPC/POPG liposomes adhered almost instantly on the sensor surface forming a lipid layer with an average modeled thickness of ~ 19 nm (n = 6). The averaged modeled thickness of the EggPC/POPG lipid layer in this study closely resembles the modeled thickness of liposome layers reported in the literature, i.e. 22 nm for a POPC liposome layer on a gold coated quartz crystal sensor [57] and 17 nm for an EggPC/POPS liposome layer on a gold coated quartz crystal sensor functionalized with $\text{H}_2\text{C}=\text{CH}-(\text{CH}_2)_9\text{-PEG}-(\text{CH}_2)_{10}\text{-SH}$ [58]. These studies in combination with the fact that the adsorption of EggPC/POPG liposomes on the polybrene coated sensor surface is accompanied with a large dissipation change, strongly suggest that the EggPC/POPG liposomes adsorb on the polybrene coated sensor surface as intact liposomes. Other studies in the literature, however, have reported a larger modeled layer thickness in the range of 33 – 42 nm for adsorbed liposome layers on oxidized gold, TiO_2 , and Al_2O_3 surfaces [59, 60]. This, on the other hand, suggests that the EggPC/POPG liposome layer adsorbed on the polybrene coated sensor surface is composed of highly truncated liposomes caused by the strong electrostatic interaction between the negatively charged liposomes and the positively charged polybrene surface. Liposome adsorption was also tested if the polybrene coating step was skipped before an analysis. The results showed that the liposomes still adhered to the sensor surface, unless the sensor was treated with a boiling solution of the oxidative cleaning mixture (i.e. $\text{NH}_4\text{OH}/\text{H}_2\text{O}_2/\text{H}_2\text{O}$). This suggests that polybrene was not totally removed during the surfactant/sodium hydroxide/ethanol cleaning step.

There was almost no observable effect on the adsorbed EggPC/POPG liposomes when both phosphonium ILs at a concentration of $2.8\ \mu\text{M}$ ($10^{-4}\%$ m/v) were allowed to interact with the liposome layer (Figure

4). A frequency decrease was, however, observed when the liposome layer was exposed to higher concentrations of the ILs. In the case of [P₈₄₄₄]Cl, a concentration of 0.28 mM (10⁻³% m/v) and higher induced a fast decrease in the frequency within 2 minutes, whereafter the frequency stabilized at a constant level. At the same time a slight initial decrease in the dissipation was observed using a [P₈₄₄₄]Cl concentration of 0.28 mM, whereas a large increase in dissipation was observed at higher concentrations of [P₈₄₄₄]Cl (Figure S2). This behavior was also reflected in a continuous increase in the modeled thickness of the liposome layer at [P₈₄₄₄]Cl concentrations higher than 0.28 mM. However, decrease in frequency, increase in dissipation, and increase in the modeled layer thickness all reversed their trend when exposing the liposome layer to a [P₈₄₄₄]Cl concentration of 28 mM (1% m/v) for over 3 minutes. The increase in frequency and decrease in dissipation continued even after the 28 mM [P₈₄₄₄]Cl solution was changed to buffer. At the end of the measurements, the dissipation had dropped to a three times smaller value than the maximum dissipation value, and the modeled layer thickness was in the range of 3.1 to 13.5 nm (Figure 4 and S2). This indicates that the remaining lipid layer is a mixture of lipid bilayers and unruptured liposomes. These findings show that [P₈₄₄₄]Cl interacts with the liposomes either by adsorbing on the liposome surfaces or incorporating into the bilayer at low concentrations, while at higher concentrations its abundance in the liposome bilayer reaches a level that destabilizes the lipid bilayer structure of the liposomes, consequently inducing liposomes to rupture and fuse. Similar frequency/dissipation have recently been observed with DPPC supported lipid vesicles interacting with melittin [61]. The effect is called “carpet” mechanism where interacting compound first adsorbs onto the phospholipid layer and after a certain amount of time, when a threshold value is reached, insertion into the lipid bilayer begins. This is followed by membrane perforation, peptide–lipid complexes and water are released, and eventually an SLB is formed [61, 62]. The same scenario is also supported by the relaxation time which illustrates the visco-elasticity of an adsorbed layer. The higher the relaxation time the longer it takes for a material to get into its original shape after an elastic deformation. When [P₈₄₄₄]Cl

363 was exposed to liposomes, the relaxation time increased until the concentration reached 28 mM (1%).
364 Hereafter, the relaxation time dropped due to the rupturing of the liposome layer (see Figure 5).
365
366 When the EggPC/POPG liposome layer was allowed to interact with [P₁₄₄₄₄]Cl concentrations of 10⁻³ %
367 (m/v) and 10⁻² % (m/v) the frequency decreased quickly and leveled out at a constant value within ~2
368 minutes, while the dissipation simultaneously increased (Figure 4 and S3). This is also reflected in the
369 modeled layer thickness, as well as in a constant increase in the relaxation time (Figure 6). These results
370 show that the interaction of [P₁₄₄₄₄]Cl with the adsorbed liposome layer causes both a mass increase and
371 a change in the mechanical properties of the liposome layer; hence, the interaction of [P₁₄₄₄₄]Cl
372 destabilizes the lipid bilayer of the liposomes by incorporation into the bilayer, thus compromising the
373 neat lipid bilayer structure. Hexadecyltrimethylammonium bromide (CTAB) which is similar in structure
374 to [P₁₄₄₄₄]Cl has recently been shown to decrease the degree of organization of an DPPC liposome bilayer
375 [63]. When the concentration of [P₁₄₄₄₄]Cl increased above its CMC (~ 0.6 mM; see section 3.1) to 2.30
376 mM (0.1% m/v) the frequency increased and the dissipation decreased quickly back to the zero level.
377 This is a clear indication that the liposome layer was completely compromised and removed from the
378 sensor surface by dissolution of the phospholipids into [P₁₄₄₄₄]Cl micelles. Mechanics of observed
379 disintegration could be similar to a three-step process of interaction of POPC giant unilamellar liposomes
380 with cetylpyridinium chloride (CPC): first the CPC was incorporated into the bilayer structure; then an
381 ellipsoidal change in the liposome shape was observed just before a membrane saturation with CPC; and
382 finally the POPC bilayer was solubilized after the saturation threshold was reached [64].
383
384 In addition, QCM experiments on mixed systems of liposomes and ILs with the polybrene coated sensor
385 were carried out. The underlying motivation was to mimic the conditions in the CE capillary
386 measurements where premixed systems like this have been used [30]. The polycation coated sensor was

387 washed with solutions of 0.3 mM liposomes pre-mixed with 0.23 or 0.28 mM (0.01% m/v) solutions of
388 [P₈₄₄₄]Cl or [P₁₄₄₄₄]Cl, respectively. The adsorption of the EggPC/POPG/[P₈₄₄₄]Cl mixture on the
389 polybrene surface was very rapid (≈ 3 min), whereas it took almost 10 minutes for the
390 EggPC/POPG/[P₁₄₄₄₄]Cl mixture to reach an equilibrium frequency level (Figure 7). This suggests that
391 neither of the ILs tested were able to fully screen the surface charges of the negatively charged liposomes.
392 Furthermore, the adsorption of the EggPC/POPG/[P₈₄₄₄]Cl mixture caused significantly larger frequency
393 and dissipation changes, and consequently also formed a layer with a larger modeled thickness compared
394 to the EggPC/POPG/[P₁₄₄₄₄]Cl mixture (Figures 7, S4, and S5). This agrees very well with the results
395 above where it was shown that the [P₁₄₄₄₄]Cl has a stronger tendency to destabilize and compromise the
396 neat structure of the phospholipid bilayer in the liposomes compared to [P₈₄₄₄]Cl.

397

398 Based on the results above it is apparent that both ILs in this study were able to significantly alter the
399 membrane structure and viscoelastic properties of negatively charged liposomes. The industry is
400 continually opting for utilizing similar phosphonium liquids as used in this study as solvents for a broad
401 range of applications, which means that there is an overly increasing risk of their unintentional
402 environmental release. Quaternary ammonium cations, which are very close in structure to the
403 investigated ILs, are commonly utilized as disinfectants (e.g. Cetrimide containing a mixture of C12-,
404 C14-, and C16-trimethylammonium bromide). Concentrations in the range of 0.1 – 1 mass % are often
405 used in medicine either for disinfection of skin and wounds or contaminated instruments [65]. The
406 influence of CTAB in the concentration range from 10 to 50 molar percent on the morphology of
407 phosphatidylcholine SLBs was recently thoroughly investigated [63]. The results from that study showed
408 that CTAB had a clear effect on decreasing the degree of organization of the lipid bilayer. The CMC of
409 CTAB is 0.92 mM [66], which is very close to the CMC of [P₁₄₄₄₄]Cl. An effective concentration for
410 disinfection should therefore be in the concentration range studied in this work, which, on the other hand,

411 might have detrimental effects on cell membranes due to the ability of [P₁₄₄₄₄]Cl to destabilize and
412 completely compromise or dissolve phospholipid bilayers at these concentrations. Moreover, the
413 biodegradability of phosphonium ILs is substantially lower compared to ammonium, imidazolium, and
414 pyrimidinium ILs [67]. It appears that [P₈₄₄₄]Cl possesses a slightly less disruptive activity on the
415 investigated liposomes compared to [P₁₄₄₄₄]Cl mainly due to temporal incorporation effects. Our findings
416 show that ILs could potentially be harmful in aquatic environments even if pure ILs are diluted thousand
417 fold (or hundred fold for [P₈₄₄₄]Cl). Furthermore, the long-time effects of concentrations below CMC
418 should be further investigated for [P₁₄₄₄₄]Cl due to its ability to strongly associate with the phospholipid
419 membrane at concentrations as low as 10⁻³% (m/v).

420

4. Conclusions

We have performed interaction studies of two phosphonium ILs and negatively charged EggPC/POPG liposomes. The CMCs of the ILs were obtained by fluorescence spectroscopy and the optical pendant drop method. Both methods were in good agreement, indicating a good reproducibility and accuracy of the CMC values. Furthermore, QCM was used as a fast and reliable method to obtain a deeper insight into the interactions of the ILs and liposomes adsorbed on a polybrene coated silica surface. The QCM measurements showed that the long alkyl chain IL, [P₁₄₄₄]⁺Cl⁻, was associating more strongly with the liposomes compared to the shorter IL, [P₈₄₄]⁺Cl⁻. At moderate concentration both ILs caused a change in the viscoelasticity of the phospholipid membrane which is attributed to destabilization of the phospholipid membrane, thus causing the liposomes to swell. At higher concentration, [P₈₄₄]⁺Cl⁻ induced vesicle rupture, whereas [P₁₄₄₄]⁺Cl⁻ completely compromised or dissolved the liposomes at a concentration higher than its CMC. Additional experiments showed that liposomes in pre-mixed systems with sub-millimolar concentrations of ILs adhered readily to the polybrene coated silica sensor, showing that the positively charged ILs were not able to fully screen the negatively charged liposomes. We have provided evidence that new “green solvents,” such as ILs, might disturb the structural stability of phospholipid membranes even at very low concentrations and, therefore, we encourage further studies of such compounds in connection to their toxicity, especially towards aquatic organisms.

438 **Acknowledgment**

439 Financial support from the Academy of Finland, project numbers 266342 (SKW), 276075 (SKW),

580 **Figure 7.** QCM graphs of normalized overtone frequencies (3rd, 5th, 7th, and 9th) and modeled thickness
581 of liposome layers for three subsequent runs for A) $[P_{8444}]Cl$ and liposomes premixed system washing of
582 the polybrene coated crystal; B) $[P_{14444}]Cl$ and liposomes premixed system washing of the polybrene
583 coated crystal. *Sensor pretreatment (400 second steps): water, 0.1 mM NaOH, water, 1% (w/w)*
584 *polybrene, water. Measurement sequence: A) sodium phosphate buffer (60 s), EggPC/POPG +*
585 *$2.8 \cdot 10^{-2}$ mM $[P_{8444}]Cl$ (600 s), sodium phosphate buffer (1000 s). B) sodium phosphate buffer (60 s),*
586 *EggPC/POPG + $2.3 \cdot 10^{-2}$ mM $[P_{14444}]Cl$ (600 s), sodium phosphate buffer (600 s)*
