1 GENOMIC DATA REVEAL A PROTRACTED WINDOW OF INTROGRESSION DURING
2 THE DIVERSIFICATION OF A NEOTROPICAL WOODCREEPER RADIATION
3
4

5 **ABSTRACT**
6

7 The incidence of introgression during the diversification process and the timespan following
8 divergence when introgression is possible are poorly understood in the Neotropics where high
9 species richness could provide extensive opportunities for genetic exchange. We used thousands
10 of genome-wide SNPs to infer phylogenetic relationships, calculate ages of splitting, and to
11 estimate the timing of introgression in a widespread avian Neotropical genus of woodcreepers.
12 Five distinct introgression events were reconstructed involving taxa classified both as subspecies
13 and species including lineages descending from the basal–most split, dated to 7.3 million years
14 ago. Introgression occurred between just a few hundred thousand to about 2.5 million years
15 following divergence, suggesting substantial portions of the genome are capable of introgressing
16 across taxa boundaries during a protracted time window of a few million years following
17 divergence when reproductive isolation is incomplete and introgression is possible. Despite this
18 protracted time window, we found that the proportion of the genome introgressing (6 to 11%)
19 declines with the time of introgression following divergence, suggesting that the genome
20 becomes progressively more immune to introgression as reproductive isolation increases.

INTRODUCTION

Genomic datasets have now made it clear that hybridization is a process that often occurs during the diversification process (Taylor and Larson 2019). Following population divergence from a common ancestor, diverging lineages possess a time window during which incomplete reproductive barriers may allow for hybridization and introgression to influence the diversification process. Shortly after population differentiation, introgression may be highly prevalent given insufficient time to accumulate reproductive barriers, leading to population fusion upon secondary contact (Rhymer and Simberloff 1996; Taylor et al. 2006; Kearns et al. 2018). Such population fusion has the effect of hindering diversification and is likely to play a key role in accelerating extinction rates in regions where taxa come into geographic contact after short durations in allopatry (e.g. high latitudes: Weir and Price 2011a; Cutter and Gray 2016). In contrast, during late stages of speciation, hybridizing taxa may be unlikely to experience introgression because sufficient numbers of genetic incompatibilities render the genome largely immune to introgression (so called “genomic speciation”: Gompert et al. 2017; Nosil et al. 2017; Pulido-Santacruz et al. 2018). However, at intermediate levels of divergence, genetic incompatibilities may render hybrids less fit, thereby preventing species differentiation upon geographic contact, but may be of insufficient number to render the majority of the genome immune to introgression. Genomes at this stage may be semipermeable to introgression, with neutral portions of the genome not closely linked to genetic incompatibilities introgressing freely, while adaptive introgression may occur at genes in which alleles convey an adaptive advantage in a heterospecific genomic background (Barton 1979; Harrison 1993; Harrison and Larson 2014; Payseur and Rieseberg 2016). Introgression at this intermediate stage could positively influence

diversification. For example, adaptive introgression of alleles conveying resistance to diseases (Deng et al. 2016) or ecological adaptation (Whitney et al. 2010; Jones et al. 2018) could allow a species to expand its geographic range leading to increased opportunities for allopatric speciation and diversification and even promote adaptive radiations (Meier et al. 2017; Marques et al. 2019). Reproductive isolation could also be promoted when populations of a species each exchange genetic material with different donor species, leading to the accumulation of genetic incompatibilities between populations (e.g. Corcoran et al. 2016). Despite the importance of introgression in either hindering or aiding diversification, we still have only a limited understanding of the prevalence of introgression, the length of the time window following divergence when introgression is possible and the proportion of the genome that is capable of introgressing. This is especially true of tropical regions which have received relatively less study compared to high latitude species.

High species richness in the Neotropics may provide extensive opportunities for introgression during diversification and a few studies have found evidence for introgression in groups that are rapidly diversifying (e.g. *Heliconius* butterflies: Mallet et al. 2007; Pardo-Diaz et al. 2012; Martin et al. 2013; Merot et al. 2017, freshwater *Xiphophorus* fishes: Cui et al. 2013; Schumer et al. 2013, 2016, island radiations such as *Geospiza* finches: Grant and Grant 2015; and recently derived groups such as high Andean siskins; Beckman et al. 2018). Several key factors may affect the prevalence of introgression in continental radiations of the Neotropics. First, traits important for both pre-zygotic (e.g. song and plumage colouration in birds; Martin et al. 2010; Weir and Wheatcroft 2011; Weir et al. 2012) and extrinsic post-zygotic (e.g. climatic niche in birds; Lawson and Weir 2014) reproductive isolation are known to evolve more slowly than at high latitudes in some groups. A comparative analysis quantifying response to song playback

between more than 89 pairs of closely related allopatric species and subspecies estimated that Amazonian taxa take about 3 million years of separation for aggressive levels to heterotypic playback to decline to half that seen in response to playback of their own taxon's song (Weir and Price 2019). In contrast, high latitude taxa require only half a million years to achieve the same level of song discrimination. Slow tropical evolution of species recognition may allow for introgression for a longer time window following divergence from a common ancestor, compared to high latitudes. Analysis of ages of avian species pairs with hybrid zones demonstrate that all latitudes contain young species pairs with hybrid zones, but hybrid zones persist in some Neotropical species that diverged from a common ancestor as long as 4 million years ago (Mya) (Weir et al. 2015; Pulido-Santacruz et al. 2018), demonstrating a protracted period when premating isolating barriers are poorly developed and hybridization is possible. Second, tropical avian species achieve secondary sympatry at a slower rate compared to high latitude species. The delay in sympatry may result from the slow rate of evolution, with taxa getting stuck for long periods of time in a parapatric state with their geographic ranges separated by narrow hybrid zones (Weir and Price 2011a). Prolonged parapatry of incompletely reproductively isolated taxa in the tropics may increase opportunities for introgression during the diversification process.

Introgression in the Neotropics could also be promoted by weak or semipermeable geographic barriers. For example, Amazonian rivers are often believed to form barriers to gene flow promoting diversification of understory forest birds and other groups (e.g. Haffer 1997; Naka and Brumfield 2018). However, recent studies have demonstrated the frequent occurrence of hybrid zones in headwater regions where rivers cease to act as dispersal barriers during interglacial periods of maximal forest expansion (Haffer 1997; Naka et al. 2012; Weir et al. 2015; Pulido-Santacruz et al. 2018), and introgression during the diversification process could be

common. Rivers may also experience periods of course changes which transfer local populations from one river bank to the other, leading to introgression. Other Neotropical geographic barriers may also be leaky. For example, temporary (and perhaps periodic) wet forest corridors have previously been proposed to have connect lowland wet forests of the Amazon and Central America and of the Amazon and the Atlantic forest of Brazil during wetter periods and may have likewise provided brief periods for geographic contact and introgression during the diversification process (Gentry 1982; Costa 2003; Batalha-Filho et al. 2013).

Our ability to generate large-scale genome-wide datasets opens a promising avenue for investigating the genomic signatures of hybridization during the evolutionary history of diversification in the Neotropics. In particular, the presence of hybridization during diversification can now be better distinguished from other processes such as incomplete lineage sorting. One test – ABBA / BABA – has been specifically useful in differentiating hybridization between lineages from incomplete lineage sorting using genome-wide SNP datasets (Green et al. 2010; The Heliconius Genome Consortium 2012; Eaton and Ree 2013; Martin et al. 2014; Fontaine et al. 2015). This test utilizes four species – one outgroup and three in-group species – and analyzes how bi-allelic SNPs (with alternative alleles coded as A and B) evolve along the phylogeny for these four species (see Fig. 2). Of the three ingroup species, species 1 and species 2 are most closely related (carrying different alleles A and B), species 3 carries the derived allele (B). Hence, there are two possible configurations: either (((A,B)B)A) or (((B,A)B)A). If no hybridization has occurred and under the hypothesis of shared ancestral polymorphism, the number of loci exhibiting ABBA and BABA configurations are expected to be equal. Deviations from that expectation are interpreted as evidence of introgression between species 3 and species 1 (if there is an excess of BABA patterns) or species 2 (if there is an excess of ABBA patterns)

(Durand et al. 2011). Related tests allow for the proportion of the genome introgressing between two species to be estimated (Martin et al. 2015)

Here, we used the ABBA-BABA and related statistics to determine the timing, prevalence and magnitude of introgression events during the diversification of a Neotropical avian genus – the *Dendrocincla* woodcreepers. This genus is distributed in humid forests throughout lowland regions of Central and South America as well as in cloud forest along the Andes (Hoyo et al. 2003). Beginning *ca.* 7 Mya (Weir and Price 2011b), *Dendrocincla* has diversified into a total of 26 subspecies which are grouped into six currently recognized species: *D. tyrannina*, *D. merula*, *D. fuliginosa*, *D. homochroa*, *D. anabatina*, and *D. turdina* (Remsen Jr. et al. 2018). Phylogeographic analysis has demonstrated that a number of subspecies are deeply diverged genetically (Weir and Price 2011b; Schultz et al. 2019), and some of these could represent distinct species. Available phylogenetic studies of the genus are based on just a few loci and show no consensus on deeper level phylogenetic relationships as well as between some of the relationships between subspecies within species (Derryberry et al. 2011; Weir and Price 2011b; Schultz et al. 2019). These inconsistencies may be the result of insufficient data or errors in inference. Alternatively, hybridization between species and subspecies may account for conflicting topologies.

Dendrocincla is typical of many morphologically cryptic, understory forest bird groups of the Neotropics, thus is a good group to test for introgression during the diversification process because many species or subspecies are parapatric (e.g. come into geographic contact with no more than 100km of geographic overlap) or sympatric, thus increasing the odds of introgression, and at least one pair of deeply diverged subspecies currently forms a hybrid zone where their populations come into geographic contact (*Dendrocincla f. atrirostris* and *D. f. rufolivacea*)

(Weir et al. 2015). This hybrid zone is remarkable because the subspecies pair are estimated to have diverged from a common ancestor *ca.* 2.5 to 3 Mya, demonstrating incomplete reproductive isolation despite their old age. This hybrid zone includes both early-generation hybrids and backcrossed individuals, suggesting that introgression between deeply diverged *Dendrocincla* taxa may be possible (Weir et al. 2015). However, whether strong selection against backcrossed individuals effectively prevents the movement of heterospecific alleles outside of hybrid zones such as this one, is unknown for *Dendrocincla*. If loci are capable of escaping the hybrid zone region and introgressing into the allopatric regions of a species' geographic range, then a genomic signature of introgression may be commonly detected during diversification.

A robust species tree for the whole genus using genome-wide data is necessary to determine the frequency and magnitude of introgression and the length of the time window following divergence when introgression is possible. Here we use genome-reduction Genotyping-by-Sequencing (GBS; Elshire et al. 2011) to build a species tree and to test for a genome-wide signature of introgression using the ABBA/BABA testing framework. We predict that introgression will be absent between allopatric taxa that are geographically distant, will be most likely between allopatric taxa that are geographically proximate and between parapatric taxa whose ranges abut. In contrast, we expect minimal introgression from broadly sympatric taxa. Despite providing the greatest geographic opportunity for introgression, sympatric taxa generally have developed substantial reproductive isolation thus limiting opportunities for introgression (Weir and Price 2011a). We also predict that the proportion of the genome introgressing will be inversely related to the time since divergence from a common ancestor with introgression occurring a short time after divergence allowing both neutral and selected loci to introgress while

introgression occurring long after divergence will be restricted to a much smaller proportion of the genome due to a longer period for intrinsic post-mating isolation to develop.

METHODS

Population sampling

We obtained genetic data for 87 specimens, representing all six recognized species and 19 of 26 species and subspecies in the genus (Figure 1 and Table S1 in supporting information). Importantly, a recent phylogeographic study (Schultz et al. 2019) sequenced a single nuclear gene and mitochondrial DNA for all subspecies of *D. fuliginosa* and found that the four subspecies which we failed to sample do not represent genetically diverged lineages but rather were nested phylogenetically within subspecies we did sample (e.g. *D. f. lafresnayeri* is nested within the sampled *D. f. ridgwayi*; *D. f. deltana* and *D. f. barinensis* were nested with the sampled *D. f. meruloides*; *D. f. phaeochroa* was nested with the sampled *D. f. neglecta*). We thus had complete sampling of all phylogenetically distinct subspecies within *D. fuliginosa*. Specimens and tissue samples were collected during field expeditions to Panama: from February to May 2004, Brazil: from April to July 2012 and January to March 2015, or were obtained from The Field Museum of Natural History (FMNH), Museu Paraense Emilio Goeldi (MPEG), University of Kansas Natural History Museum (UK), Louisiana State University Museum of Natural Science (LSUMZ) and Smithsonian Tropical Research Institute (STRI).

DNA isolation and SNP genotyping

Genomic DNA was extracted from blood or muscle tissue using the EZNA Tissue DNA Kit (Omega Bio-Tek). DNA was concentrated to 30 ng/ul, quantified with picogreen and sent to the Cornell Institute for Genomic Diversity for Genotyping by Sequencing (GBS; Elshire et al. 2011). With this method, the genomic DNA of each individual was randomly digested using the PstI restriction enzyme and multiple libraries were constructed (these included both *Dendrocincla* and other passerine samples), with 95 individuals uniquely barcoded in each library and each library sequenced on a single lane of Illumina HiSeq 2000 platform. We obtained a total of 978,473 raw reads for all specimens and used the STACKS pipeline v 1.35 (Catchen et al. 2013) for de-multiplexing, to prune adaptor sequence and to trim reads to 90 base pairs. Single-nucleotide polymorphisms (SNPs) were called using the reference genome pipeline of STACKS 2.4 (Catchen et al. 2013). We used an unpublished reference genome of another woodcreeper species (*Xiphorhynchus elegans*) for this pipeline. Briefly, to generate this reference, we sent pectoral muscle from a single individual of *Xiphorhynchus elegans* (collector number JTW1128) to Hudson Alpha who generated a single Chromium X library which was paired-end sequenced (with median 306 bp insert size) along with one other avian genome on a single lane of HiSeq X. We assembled the 522 million reads using default settings in Supernova 1.2.2 (Weisenfeld et al. 2017). The resulting genome assembly comprised 1680 scaffolds greater than 10 Kb in length, a contig N50 of 108 Kb, a scaffold N50 of 2.04 Mb, an assembly size (including only scaffolds greater than 10 kb) of 994.1 Mb (slightly smaller than the expected 1.1 to 1.2 Gb size typical for passerine birds) and a mean depth of coverage of 43x. De-multiplexed *Dendrocincla* reads were aligned to the reference using the very sensitive option of Bowtie2 v 2.3 (Langmead and Salzberg 2012) and SNPs were called using *ref_map.pl* routine from STACKS 2.4 (Catchen et al. 2013).

Three datasets were extracted and filtered using VCFtools v 0.1.16 (Danecek et al. 2011):

A) The phylogeny dataset used to generate a maximum likelihood phylogeny and a species tree for all 87 individuals. A minimum depth of coverage of 5x was required to retain a genotype call for an individual at a given locus and loci with more than 75% of individuals with missing calls were excluded. To reduce the probability of retaining SNPs artificially generated by aligning paralogues together, we excluded SNPs that had very high coverage (exceeding the 95th percentile) and for which more than 75% of diploid samples were heterozygous. SNPs in which the minor allele had fewer than three copies (unlikely to be phylogenetically informative) were excluded and SNPs were thinned to at most 1 SNP per 10,000 bp. Heterozygous individuals for a SNP were coded with standard ambiguity codes. A total of 24,130 SNPs were retained.

B) ABBA/BABA dataset. We extracted the individual representative of each taxon with highest coverage (19 individuals). As the ABBA / BABA test utilizes haploid sequences (i.e. a random allele is chosen for each heterozygous site) accurate genotype calls using high depth of coverage is not required. To increase the number of loci retained, we filtered individuals to have a minimal depth of coverage of only 3x. We applied the other filters used in the phylogeny dataset except that we allowed SNPs to be every 5,000 bp apart (to retain more SNPs). For every set of four sequences (e.g. P1, P2, P3 and Outgroup) used in an ABBA / BABA test, SNPs with missing data were excluded and individuals with sequenced copies of both alleles at a SNP were randomly assigned one of the two alleles. These final datasets of four sequences ranged in size 2,030 to 6,174 SNPs.

C) G-PhoCS datasets. For the same 19 individuals used in the ABBA / BABA dataset we used the same filtering strategy except we required a higher minimum depth of coverage (8x) and required that all individuals have genotype calls in order for a SNP to be retained. We thinned SNPs to be at least 10,000 bp apart. We then extracted the 90 base pair

reads associated with these SNPs for a final dataset of 390 loci totalling 35,100 nucleotide positions. These loci often had multiple SNPs.

Phylogenetic analyses

We generated a maximum likelihood phylogeny from our concatenated dataset of 24,130 SNPs using IQTree 1.6.10 (Nguyen et al. 2015). The phylogeny was used to assess whether subspecies are monophyletic. Leaché et al. (2015) demonstrated that topologies estimated with concatenated SNPs (invariant sites removed; as done here) are very similar to topologies estimated with full sequences, hence suitable for phylogenetic inferences. We used *Deconychura* as an outgroup, generally used default options but allowed the program to estimate the best model of sequence evolution and used 1,000 bootstrap analyses to assess node support on the maximum likelihood tree (options: -st DNA -m MFP+MERGE -bb 1000 -redo).

A species tree was then inferred using the coalescent-based quartet method SVDquartets (Chifman and Kubatko 2014) implemented in PAUP* v4a165 (Swofford 2002). All 87 individuals were assigned to their respective species or subspecies and used to estimate the topology. SVDquartets took the set of 24,130 bi-allelic SNPs (coded as nucleotides) and inferred quartet trees for all subsets of four species. SVDquartets assumes each site has its own genealogy drawn from the coalescent model and has been shown to perform better as compared to other methods for species inference when gene flow is present (Chifman and Kubatko 2014; Long and Kubatko 2018). We sampled all possible quartets and the true quartet topology for each sampled quartet was inferred using the lowest SVD score. We assembled the set of inferred quartet trees into a species tree using a modified version of the Quartet FM algorithm called QFM in PAUP*(Reaz et al. 2014). Uncertainty in the inferred relationships was quantified using non-

parametric bootstrapping with 1,000 replicates. *Deconychura longicauda* was used as an outgroup to root the analysis.

We fixed the species–tree topology obtained from SVDquartets (excluding the outgroup) and used the generalized phylogenetic coalescent sampler G-PhoCS v 1.3 (Gronau et al. 2011) to estimate node ages. Here node ages represent dates of population splitting. Sixteen independent 200 million step runs of G-PhoCS were obtained, each using a 10,000 step burn-in and with every 10th step in the post burn-in sampled. Post burn-in samples were pooled across the 16 runs and median node ages and 95% confidence intervals were obtained for each node. We calibrated the median node age for the basal split within *Dendrocincla* with an age of 7.3 Mya obtained from a previously dated mitochondrial phylogeny for the genus (Weir and Price 2011b) which used the Passerine mitochondrial mutation rate of 2.1% (Weir and Schluter 2008). This calibration approach assumes that there has been no mitochondrial DNA introgression across the basal node in *Dendrocincla*. The higher-level topology of the mitochondrial phylogeny is identical to that uncovered here for our genome-wide nuclear dataset suggesting that if mitochondrial introgression did occur, it likely happened shortly after initial divergence and thus will have minimal impact on the calibration approach used here.

Test for Introgression

We constructed 239 ABBA/BABA tests (Table S2) using the topology from the species tree generated by SVDquartets. Outgroup taxa should be free of introgression. Given that we found evidence of introgression between lineages descending from the basal-most node in *Dendrocincla*, we restricted our use of outgroup to *Deconychura longicauda* which is closely related to *Dendrocincla* (Derryberry et al. 2011). Only loci with ABBA or BABA allelic

configurations for P1, P2, P3 and O are used in which A and B are alternative alleles for a bi-allelic SNP.

Introgression may have occurred between current taxa that appear at the tips of the phylogeny or may have occurred deeper in the phylogeny between ancestral lineages which have since diverged into clades of multiple tip taxa. Here we used the principle of parsimony to estimate the total number of introgression events and to determine where on the phylogeny introgression occurred and the approximate time of introgression (see Fig. 3). For example, we assumed that if all the taxa in a clade (each treated as a P3 species in multiple ABBA/BABA tests) showed evidence of significant introgression with a P1 or P2 species, then a single introgression event occurred involving the ancestor of the P3 clade rather than multiple introgression events involving each P3 species (see example in Fig. 3B). This parsimony approach also had the effect of reconstructing the timing of introgression to have occurred closer to the time of divergence when reproductive isolation would be less well developed, and introgression would have been more likely.

For the example phylogeny of five extant taxa in Fig 3, eight ABBA/BABA tests would be performed and would allow us to infer whether introgression involved terminal branches or internal branches of the phylogeny. The timing of introgression can then be determined by using the younger of the two ancestral nodes leading to the two lineages as the oldest time when introgression could have occurred while the youngest time for introgression would be the age of the oldest of the daughter nodes immediately descending from these lineages or would be the present if both lineages are tip taxa (see example in Fig. 3B). The ABBA/BABA approach tests for introgression between most pairs of lineages, both at the tips as well as ancestral lineages represented by internal branches, but cannot be used to test for introgression between sister

lineages including sister taxa at the tips of a phylogeny or between ancestral sister lineages (e.g. the two immediate branches descending from the basal split within a phylogeny).

ABBA/BABA tests were conducted in R using the package *evobiR* (Blackmon and Adams 2015). Standard errors and significance were assessed using 10,000 bootstrap datasets. Statistical significance of D was calculated by converting the range of standard errors into a two-tailed p -value, and using $\alpha=0.005$ as a conservative cut-off following other authors (Eaton and Ree 2013; Streicher et al. 2014), which have also found that significant D values can be obtained from very few SNPs following the ABBA/BABA pattern. We agree with these authors in reporting tests as significant only when at least 50 SNPs with ABBA or BABA patterns were present.

For significant ABBA / BABA tests we used the f_{hom} statistic (Martin et al. 2015) to estimate the proportion of the genome that experienced introgression. This statistic replaces either the P1 or P2 species that had an excess of the derived allele (B) with the P3 species. Thus, rather than testing P1, P2, P3 and Outgroup, we test P1, P3, P3 and Outgroup for a test in which P2 shared more derived alleles with P3. The statistic follows:

$$f_{\text{hom}} = (\text{ABBA1} - \text{BABA1}) / (\text{ABBA2} - \text{BABA2}) \quad \text{Equation 1}$$

where ABBA1 and BABA1 refer to the original number of ABBA and BABA SNPs for the P1, P2, P3, Outgroup test while ABBA2 and BABA2 refer to the number for the test where P1 or P2 (which ever has greatest number of derived alleles) is replaced with P3. This statistic provides an estimate for the proportion of the genome that has introgressed and assumes that P3 introgressed into P1 or P2 rather than the reverse. For further details and rationale see Martin et al. 2015.

We used least squares regression to fit a linear model (R function *lm*) and non-linear least squares regression (R function *nls*) to fit a model of exponential decay to model the change in f_{hom} as a function of lineage age when introgression occurred. The two models had the form:

$$f_{\text{hom}}(t) = f_{\text{hom}0} - bt \quad \text{Equation 2}$$

$$f_{\text{hom}}(t) = f_{\text{hom}0} + K(1 - \exp(-Kt)) \quad \text{Equation 3}$$

where $f_{\text{hom}}(t)$ is the value of f_{hom} for lineages of age t when introgression occurred, $f_{\text{hom}0}$ is the proportion of the genome introgressing when lineage age is 0 and b is the slope of the linear and K is a parameter of the exponential decay model. The exponential decay model was chosen because it roughly approximates the expected decline in hybrid fitness when reproductive isolation is driven mostly by the accumulation of genetic incompatibilities. The two model fits were compared with Akaike Information Criterion (AIC) and the one with the lowest AIC value was chosen as best fit.

RESULTS

Phylogenetic relationships

The maximum likelihood phylogeny of concatenated SNPs produced a generally well supported topology with most taxa monophyletic (Fig 4). Most subspecies were monophyletic with strong support with three exceptions: support for monophyly of *D. m. merula* and *D. m. obidensis* was low, *D. m. castanoptera* was paraphyletic with respect to *D. m. badia* (with our sole sample of *D. m. castanoptera* from the interfluvium between the Xingu and Tocantins rivers grouping with *D. m. badia*, suggesting that populations from this interfluvium should either be transferred to *D. m. badia* or be recognized as a new subspecies) and the two samples of *D. f.*

meruloides were nested within those of *D. f. neglecta*, contrary to two studies which found these taxa to be reciprocally monophyletic, but whose analyses were based on few genes and were dominated by a mitochondrial DNA signal (Weir and Price 2011b; Schultz et al. 2019).

Phylogenetic analysis in SVDquartets produced a robust species tree (Fig 5). Phylogenetic relationships among 18 *Dendrocincla* taxa tested were generally well-supported, with only three nodes showing bootstrap values less than 95% and only one node with bootstrap support less than 80% (Fig. 5). Relationships among taxa were identical on the maximum likelihood and species trees. Five of the six currently recognized species within *Dendrocincla* are monophyletic (*D. tyrannina*, *D. merula*, *D. turdina*, *D. homochroa*, *D. anabatina*) with *D. fuliginosa* paraphyletic with respect to *D. anabatina*. Previous analyses recovered a strong sister relationship between *D. f. ridgwayi* and *D. f. meruloides* (Weir and Price 2011b). Here we found that *D. f. neglecta* and *D. f. meruloides* are sisters and that *D. f. ridgwayi* is the next closest relative to these. Additionally, *D. f. fuliginosa* and *D. f. rufoolivacea* are more closely related to one another than with *D. f. atrirostris*, and there is strong support for the placement of *D. f. atrirostris* which was previously uncertain when analyzing only a small number of genes (Weir and Price 2011b; Schultz et al. 2019). An earlier study recovered low support for the sister relationship between *D. merula* and *D. tyrannina* (Weir and Price 2011b). Here, this relationship is strongly supported.

Dates of population splitting estimated on the species tree topology using G-PhoCS suggest an early divergence between the *D. tyrannina* complex and the *D. merula* complex, which happened shortly after the basal split within the genus (Fig. 5). Likewise, *D. homochroa* and the *D. fuliginosa* / *D. anabatina* / *D. turdina* clade split from a common ancestor shortly after the basal split. Our dating suggests a date of splitting between *D. turdina* and *D. fuliginosa* / *D. anabatina* of ca. 5 Mya consistent with the recent recognition of *D. turdina* as a species distinct

from *D. fuliginosa* to which it was once considered conspecific. Likewise, *D. m. merula* and *D. m. obidensis* diverged from other subspecies in the *D. merula* complex between 4 and 5 Mya consistent with two distinct species, as has previously been suggested (Willis 1979). *D. m. merula* and *D. m. obidensis* have a reddish-brown rather than a gray or blue-gray iris found in the remainder of the complex, they are substantially larger, have darker overall plumage, and appear to be differentiated in both song and calls (though a systemic review of vocalizations is needed). The differences in behaviour, size, plumage, and genetics together with the lack of evidence from ABBA / BABA tests for introgression with other members of the complex (see below) lead us to recommend its treatment as a distinct biological species.

The sampled subspecies of the *D. fuliginosa* / *D. anabatina* complex clade indicate a protracted history of divergence dating back to about 3 Mya when *D. f. atrirostris* diverged from the remainder of the complex. The placement of *D. anabatina* within *D. fuliginosa* renders the latter paraphyletic. A sensible approach would be to recognize four clades within the complex that diverged between two and three million years ago as distinct biological species: 1) *D. f. atrirostris*, 2) *D. anabatina* (which is sympatric with *D. f. ridgwayi* and thus represents a distinct biological species), 3) *D. f. fuliginosa* together with *D. f. rufoolivacea*, and 4) the clade containing *D. f. ridgwayi*, *D. f. neglecta*, and *D. f. meruloides* (and also including the unsampled *D. f. lafresnayeii*, *D. f. barinensis*, *D. f. phaeochroa*, and *D. f. deltana* subspecies). However, despite its deep phylogenetic divergence, *D. f. atrirostris* is very similar morphologically and in song to the geographically adjacent *D. f. rufoolivacea* with which it forms a hybrid zone (Weir et al. 2015). Nevertheless, the hybrid zone appears to be narrow and we find no evidence from the ABBA / BABA test indicating that introgression has occurred between these two lineages, arguing for their species status. Two other old but cryptic lineages have geographically

concordant hybrid zones and show clear signs of strong post-mating reproductive isolation (Pulido-Santacruz et al. 2018). Further work will be needed to determine if younger members of the *D. fuliginosa* complex are also specifically distinct.

Test for introgression

Fifty nine ABBA / BABA tests met our minimum cut-off of possessing at least 50 ABBA or BABA sites and were tested for a significant value of *D* (Table S2). Twelve of these 59 tests uncovered significant gene flow (Table 1). Using the assumption of parsimony these would represent as few as five introgression events. All members of the *D. fuliginosa/anabatina* clade (when treated as P3) suggested introgression with *D. merula* (P1) with respect to *D. tyrannina* (P2) (Table 1). We interpret these seven tests to represent a single introgression event involving the ancestral branch preceding the *D. fuliginosa* complex and the ancestral branch preceding the *D. merula* complex. Likewise, both *D. turdina turdina* and *D. t. taunayi* (as P3) supported significant introgression with *D. f. atrirostris* (P2) which we interpret as a single introgression event between the ancestral branch preceding the *D. turdina* complex and *D. f. atrirostris*. We also found evidence of an introgression event between *D. anabatina* and the ancestor of the clade including *D. f. neglecta*, *D. f. meruloides* and *D. f. ridgwayi* (interpreted as a single event), between *D. rufolivacea* and the ancestor of *D. meruloides* and *D. neglecta* (assumed to be one event), and between *D. f. ridgwayi* and *D. f. meruloides*.

Introgression events are dated from near the present to about 5 million years ago (Fig. 6), but no events were reconstructed during the first 2 million years of the genus despite the presence of ancestral branches in the phylogeny at this time of divergence which form valid ABBA/BABA tests. Introgression happened from just a few hundred years to about 2.5 million years following

divergence from a common ancestor (Fig. 6). The proportion of introgression as measured by the f_{hom} statistic ranged from 0.051 to 0.11 for the 12 significant ABBA / BABA tests. Multiple ABBA / BABA tests supporting the same ancestral introgression events were averaged, resulting in a range of f_{hom} from 0.057 to 0.11. When testing the relationship of f_{hom} and lineage age when introgression occurred we also included *D. f. atrirostris* and *D. f. rufoolivacea* which currently possess a hybrid zone, but whose ABBA/BABA test was not significant. . The relationship between averaged f_{hom} and the time between divergence and introgression was substantially better fit by the exponential decay model ($f_{\text{hom}0} = 0.12, b = 0.0045$) than the linear model ($f_{\text{hom}0} = 0.13, b = -0.034$), with the former having an AIC value 5.9 units lower than the latter (Fig. 6B).

DISCUSSION

We used a phylogenetic approach to test for introgression among species and subspecies and found that introgression in *Dendrocincla* was fairly common (at least 5 events for a phylogeny with only 18 taxa), as has been found for other tropical (e.g. Martin et al. 2013) and temperate clades (e.g. Sullivan et al. 2014), and that it often involved the sharing of substantial amounts of the genome (ranging up to 11%). Our analyses using the ABBA / BABA test uncovered clear genetic evidence for at least five distinct introgression events between non-sister taxa. The actual number of introgression events could be higher given that the ABBA / BABA test is not capable of testing introgression between sister lineages regardless of whether these represent tip taxa, or ancestral sister branches deeper in the phylogeny. Sister lineages at the tips of a phylogeny represent the most closely related pairs of taxa, are often geographically proximate, and might thus be expected to experience the highest amounts of introgression.

Likewise, we analyzed relatively small datasets of SNPs (which ranged from 2030 to 6594 SNPs for each ABBA / BABA test; Table S2) which reduces our ability to detect introgression events involving a smaller proportion of the genome. With full genome sequences, significant gene flow was detected between Neandertal and Eurasian human lineages despite having small values of the D statistic (ranging from 0.027 to 0.058). All of our significant ABBA / BABA tests had absolute D statistics exceeding 0.23 (range 0.23 to 0.36). With full genome sequencing additional introgression events involving a much smaller genomic component might be supported. These considerations suggest that substantially more than five introgression events could have occurred in the history of this genus and indicate that introgression is likely to be a common phenomenon during diversification of Neotropical taxa such as *Dendrocincla*.

Our data suggest the time window when introgression is possible following divergence from a common ancestor ranges from zero to at least 2.5 million years (Myr) (Fig. 6A). One or two introgression events occurred less than a million years following divergence, consistent with introgression during the early stages of speciation.. In contrast, two introgression events occurred more than two million years following divergence (the oldest dating to 2.2 to 2.8 Myr between the ancestors of the *D. fuliginosa* and *D. merula* complexes), suggesting that gene flow is possible despite long periods for reproductive isolation to accumulate. These dates point to a protracted speciation process in the Neotropics in which reproductive isolation accumulates slowly and introgression across hybrid zones or over semi-permeable geographic barriers may be possible

We failed to detect introgression between *D. f. atrirostris* and *D. f. rufolivacea* for which we previously described a hybrid zone (Weir et al. 2015). Our dating suggests this pair of subspecies diverged from a common ancestor ca. 3.1 Mya. The lack of evidence for introgression

despite localized hybridization at the contact zone suggests that taxa pairs of this age may have exceeded the end of the time window when introgression remains possible. If indeed this is the case, then the lack of evidence from the ABBA / BABA test for introgression would also suggest that hybridization has likely not occurred during earlier time periods when reproductive isolation would have been weaker, perhaps because these taxa only recently came into geographic contact for the first time. We suggest that the time window of introgression in *Dendrocincla* ends sometime between 2.5 and 3.1 million years following divergence. Detailed analyses of Amazonian hybrid zones in another species pair of woodcreeper that diverged about 2.5 Mya and a four million year old pair of antbirds likewise found that despite frequent hybridization and a lack of strong premating isolation, the genome of these species pairs was essentially immune to introgression due to near complete post-zygotic reproductive isolation (Pulido-Santacruz et al. 2018). Taxa may continue to form hybrid zones for some time after the time window of introgression has closed without introgression ensuing.

The relationship between total reproductive isolation and time are predicted to differ for different classes of reproductive isolation (e.g. (Gourbière and Mallet 2010). Due to their epistatic nature, the accumulation of genetic incompatibilities (e.g. Dobzhasky-Muller incompatibilities) are predicted to snowball – that is to increase faster than linear through time (Orr 1995 p. 199; Orr and Turelli 2001; Matute et al. 2010; Moyle and Nakazato 2010) – and to result in an approximately exponential decline in hybrid fitness. In contrast, the decrease in hybrid fitness due to chromosomal rearrangements is predicted to be linear (e.g. no epistatic chromosomal evolution; Gourbière and Mallet (2010) and sources therein), while the rate of prezygotic isolation evolving under reinforcement is expected to slow down rather than speed up because the strength of selection to reinforce assortative mating declines as the frequency of

hybridization declines (Gourbière and Mallet 2010). Interestingly, the proportion of the genome introgressed for the five cases of introgression and the one contemporary hybrid zone in *Dendrocincla* appears to decline exponentially with the age of the lineages at hybridization (Fig. 6B). This result mimics the snowballing effect expected if the accumulation of generic incompatibilities drives reproductive isolation. We caution that sample size is low (n=6) and that the non-linear nature of the data is largely driven by inclusion of the present-day hybrid zone between *D. f. atrirostris* and *D. f. rufoolivacea* across which introgression is essentially zero. If the relationship holds it would suggest that the genome becomes progressively less permeable to gene flow as the number of genetic incompatibilities increases, with genome permeability essentially dropping rapidly after about 2.5 million years since divergence. Alternatively, older lineages may have had more time for introgressed genes to be eliminated by purifying selection. However, a strong relationship between the proportion of the genome that has introgressed and the time of hybridization is lacking (Fig 6C), and it seems unlikely that purifying selection would operate over such long periods.

The geographic context of introgression is also an important consideration. Broad sympatric overlap provides the greatest geographic opportunity for hybridization, parapatry along narrow contact zones provides less opportunity, while allopatry provides limited opportunity. Two of the five introgression events occurred between clades which are currently sympatric over a 500 km North-to-South stretch of Nicaragua and Honduras (between *D. anabatina* and the ancestor of a clade including *D. f. ridgwayi*, *D. f. meruloides* and *D. f. neglecta*) and over most of the Amazon basin (between the ancestor of the *D. fuliginosa* and the ancestor of the *D. merula* clades). In both cases, introgression appears to have involved an ancestral taxon during an earlier

time period when geographic overlap may not yet have been attained. As such, we have no solid evidence for introgression following attainment of broad sympatry, though introgression during a sympatric state remains possible. While sympatry maximizes geographic opportunity for hybridization, species which are broadly sympatric likely exhibit strong levels of reproductive isolation, without which they likely could not persist in sympatry. Introgression involving substantial proportions of the genome are generally unlikely for species which have attained broad sympatry, though exceptions are documented (e.g. Blue-winged / Golden winged warblers, Toews et al. (2016); Capuchinos, Campagna et al. (2017)).

Surprisingly, we failed to find any convincing cases of introgression involving currently parapatric taxa. Parapatric taxa often form hybrid zones where they come in contact which might provide an ideal opportunity for introgression, though the sole known hybrid zone in *Dendrocincla*, which we discussed above, showed no evidence of introgression using ABBA / BABA tests. Other notable examples of extensive parapatry in *Dendrocincla* failed to show significant ABBA / BABA tests (e.g. *D. f. neglecta* and *D. f. atrirostris*). We did not detect introgression between *D. tyrannina* and *D. merula* which replace each other elevationally along most of the transition between the Andes and Amazon from Colombia to Bolivia, albeit with a slight elevational gap between their ranges. Elevational differentiation may have helped to prevent introgression in this case.

Rivers often occur along the contact zones between Amazonian taxa (Haffer 1969, 1997) and may be an important driver of speciation (Haffer 1997; Naka et al. 2012; Ribas et al. 2012; Naka and Brumfield 2018). Rivers may prevent gene flow in which case taxa on opposite sides of these barriers could be considered allopatric, or they may be permeable to gene flow in which case taxa should be considered parapatric. We tested for intraspecific introgression between

subspecies of *D. merula* (*D. m. obidensis* and *D. m. castanoptera*; *D. m. obidensis* and *D. m. olivascens*) and within *D. fuliginosa* (between *D. f. fuliginosa* and *D. f. atrirostris*) which were fully separated by the main Amazon River. None of these comparisons were significant. This suggests that the Amazon river may be impermeable to gene flow or that if dispersal across this barrier does occur, then it is sufficiently rare that it is not detectable by the ABBA/BABA tests implemented on our dataset. Our results are consistent with rivers acting as drivers of speciation in which cross-river gene flow is limited.

While many high latitude species of birds are migratory and may accidentally wander into the breeding ranges of allopatric congeners, potentially leading to introgression between allopatric populations, woodcreepers and most other Neotropical passerine species tied to tropical forest show limited if any tendency to wander geographically. As such, introgression between fully allopatric taxa may be highly unlikely. Nevertheless, of the five introgression events we document, three occurred between allopatric taxa. In two of these cases, it seems likely that geographic ranges of currently allopatric taxa met during past wetter periods of forest expansion. For example, introgression between the Atlantic forest (*D. turdina*) and south-central Amazonia (*D. fuliginosa atrirostris*) was strongly supported. Both regions are widely separated by xeric forests and open habitats of the Argentinean and Paraguayan Chaco, the Cerrado and the Caatinga in north-eastern Brazil (Ab'Saber 1977). Palynological evidence suggests that these were connected in the past through gallery forests that expanded into the Chaco, Cerrado and Caatinga along two main routes (Ledru 1993; Behling 1998, 2002; Wang et al. 2002). A southern route connected the Amazon forests to the southern Atlantic Forest through the Chaco in Argentina, Bolivia and Paraguay, while a second northern route connected the northern Atlantic Forest through the Caatinga in northeastern Brazil. Comparative phylogenetic studies across

distinct co-distributed taxa (e.g. in birds: Batalha-Filho et al. 2013, mammals: Costa 2003, and amphibians: Fouquet et al. 2012) have provided additional evidence for both routes. Our results support introgression only via the southern Chaco corridor (e.g. Atlantic forest *D. turdina* introgressed with south-central Amazonian *D. f. atrirostris*). The presence of distinct crown streaking in *D. f. atrirostris* had led previous authors to place it within *D. turdina* (see Hoyo et al. 2003), which also has a streaked crown, and could represent a character that has introgressed from the Atlantic Forest to the Amazon via this route. We date this introgression event to 2.0 to 2.8 Mya suggesting that wet forest connections may have existed prior to the major glacial cycles of the mid to late Pleistocene. In contrast, we found no evidence of introgression between the Atlantic forest and south-eastern Amazonia along the northern route (e.g. no gene flow between *D. turdina* and the south-eastern Amazonian *D. f. rufolivacea*).

We also found support for introgression between the currently allopatric *D. f. ridgwayi* found in the Choco region through Central America and *D. f. meruloides* of northern Venezuela and Trinidad sometime during the past 300 kya. We did not sample the geographically intervening *D. f. lafresnayeri* of northern Colombia and Venezuela (whose range closely approaches that of *D. f. meruloides* in northern Venezuela and *D. f. ridgwayi* in Colombia). However, a recent phylogeographic analysis using mitochondrial DNA suggested that *D. f. lafresnayeri* may not be a valid subspecies, with the western part of its range nested within *D. f. ridgwayi* and the eastern half forming a monophyletic clade together with *D. f. meruloides*, *D. f. deltana*, and *D. f. barinensis* (Schultz et al. 2019). Introgression thus appears to have involved lineages which currently approach each other geographically in northern Columbia, and contact between these lineages during a wetter past interglacial period would not be unexpected.

In contrast to the above two cases where past geographic contact between currently allopatric taxa seems likely, we found one case of introgression between geographically distant allopatric taxa. Evidence of introgression between *D. f. rufolivacea* of SE Amazonia and the ancestor of *D. f. neglecta* (western and northern Amazonia) and *D. f. meruloides* (northern Venezuela and Trinidad) is hard to explain because *D. f. rufolivacea* is currently geographically separated from the other subspecies by the ranges of *D. f. atrirostris* and *D. f. fuliginosa* (Fig. 1). Whether this introgression event resulted from long distance leapfrog dispersal across the ranges of the intervening subspecies or occurred during a glacial cycle (i.e. the event is dated to the mid Pleistocene) when the range distributions of these subspecies may have had a different configuration that resulted in geographic contact, is hard to determine. The Tapajos, Madeira and other rivers in Amazonia – which often form the boundaries between geographically adjacent taxa – may have shifted their drainage patterns periodically through the Pleistocene (Hayakawa and Rossetti 2015; Ruokolainen et al. 2018) resulting in the current allopatry between taxa which were once in contact and able to introgress. Interestingly, our sample included three individuals of *D. f. neglecta* that occurred on the eastern bank of the Madeira River (MPDS 616, 748, and 749 representing the first record of this taxon on the eastern bank) within the Aripaunã-Machado mini-interfluvium. The presence of *D. f. neglecta* on the eastern bank of the Madeira may indicate a former connection once occurred in this region to the east. Biogeographic ties between this mini-interfluvium and the region east of the Tapajos river have previously been suggested for *Lepidothrix* manakins in which introgression may have occurred from the eastern *L. iris iris* into the local population of *L. nattereri* from Aripaunã -Machado (Dias et al. 2018).

We have already discussed the limitation that the ABBA / BABA test is not capable of testing introgression between sister taxa, and thus, likely underestimates the number of

introgression events. Another issue is that the D -statistic may be extreme if small windows of sampled SNPs are investigated, mainly due to the presence of a rather limited amount of unlinked information (Martin et al. 2015). To avoid this, we analyzed a genome-wide sample of SNPs (see methods) with a minimum of 2,030 SNPs for each four-taxon comparison, and we retained SNPs which were at least 10 kbp apart to help ensure that SNPs were not closely linked. Though the draft reference genome we used lacks chromosome information, it is likely that these SNPs are derived from across the genome rather than from a single genomic region.

Another issue is that significant ABBA/BABA tests might reflect parallel natural selection rather than introgression. Parallel natural selection acting on the P3 and either the P1 or the P2 taxa could result in an excess of ABBA or BABA patterns, even in the absence of gene flow between them (Durand et al. 2011). The levels of excess measured here for the significant comparisons range from 37 to 95, but the actual number of loci affected for the entire genome would conceivably be much higher given that our filtered GBS dataset only targets a small fraction of the genome (less than 1%). Whether parallel selection would affect this number of SNPs is difficult to assess. However, parallel selection would be most likely for broadly sympatric taxa that occupy similar environments, and only two of our introgression events involved taxa which currently are sympatric.

Conclusions

Hybridization has long been considered a negative process to species diversification, reducing genetic diversity through introgression. Yet, an increasing number of documented cases have recently shown that introgression is prevalent in invertebrates, aquatic vertebrates or island

radiations from the Neotropics (e.g. Mallet et al. 2007; Cui et al. 2013; Martin et al. 2013; Schumer et al. 2013; Grant and Grant 2014; Merot et al. 2017). Our analyses suggest that introgression was also fairly common within a continental radiation of terrestrial vertebrates from the Neotropics. We uncovered historical introgression events among closely and distantly related lineages of *Dendrocincla*, some of which diverged more than 7 million years ago (Weir & Price 2011a), suggesting that hybridization was present throughout the evolutionary history of the group. Our analyses support introgression events within 2.5 million years following divergence suggesting that introgression is possible even between moderately old taxa. Despite this long window when introgression is possible, we found an approximately exponential decline in the proportion of the genome introgressing with increasing time between divergence and introgression, potentially consistent with the accumulation of genetic incompatibilities which progressively render greater amounts of the genome immune from introgression until introgression ceases and “genomic speciation” (*sensu* Gompert et al. 2017) is achieved. These results are in agreement with a growing list of studies suggesting that reproductive isolation in Amazonian and other Neotropical birds develops over an extended timeframe (Martin et al. 2010; Weir and Wheatcroft 2011; Weir et al. 2012, 2015; Pulido-Santacruz et al. 2018) allowing for ample opportunities for introgression – often involving substantial amounts of the genome as documented here – during the diversification process.

Table 1. Twelve significant ABBA / BABA tests (for which $p < 0.005$) which we interpret as representing five distinct introgression events. All seven members of the *D. fuliginosa* / *D. anabatina* clade when placed as P3 tested positive for introgression with the ancestor of the *D. merula* clade. We interpret this as a single introgression event represent the ancestor of *D. fuliginosa* into the ancestor of *D. merula*. Likewise, both subspecies of *D. turdina* when placed as P3 tested significant for introgression with *D. f. atrirostris* which we interpret as a single introgression event involving the ancestor of *D. turdina*. The last column denotes gene flow events colour coded in Figure 5. *D* represents the *D* statistic and SE is the standard error. f_{hom} is an estimate of the proportion of the genome introgressing.

FIGURES LEGENDS

Figure 1. Geographic range of *Dendrocincla* species and subspecies and sampling localities.

Borders between subspecies are approximate. Sample localities (Table S1 in supporting information) are shown by black circles. Major Amazonian rivers shown by blue lines. Ranges adapted from Weir and Price 2011b.

Figure 2. Illustrative example for the ABBA/BABA test to quantify introgressive gene flow between lineages in a four-taxon phylogeny (P1, P2, P3 and Outgroup). ABBA's and BABA's are SNPs at which either P2 and P3 shared the derived allele "B" (ABBA) or P3 and P1 (BABA) shared the derived allele "B". The red line represents two possible origins of the derived allele through sorting of ancestral polymorphism. ABBA's and BABA's should occur with equal frequency if derived solely through the sorting of ancestral polymorphism. Alternatively, significant differences of the number of ABBA versus BABA sites suggests introgression. The illustrated example had a significant excess of ABBA's suggesting gene flow between P3 (*Dendrocincla fuliginosa ridgwayi*) and P2 (*D. f. neglecta*) shown by black arrows, but does not indicate whether gene flow was bidirectional, or unidirectional from P3 into P2 or from P2 into P3. As implemented here, P1 is fully allopatric to P3, while P2 and P3 are in close geographic contact (either sympatric or parapatric, see main text for details). Bird illustrations are reproduced as they are in Handbook of the Birds of the World Alive with the permission of HBW Alive Lynx Edicions Barcelona.

Figure 3. Example implementation of the ABBA / BABA test. A) Phylogeny of five species eight ABBA / BABA tests are applied in such a way as to test for introgression between both lineages that terminate at the tips of the phylogeny in extant taxa (numbered 1 to 5) as well as past lineages that occupy interior positions of the phylogeny (labelled A1 to A3). Introgression can be tested between most lineages but cannot be tested between sister lineages (e.g. 2 and 3; 4 and 5; 1 and A1; A2 and A3). Tests in which interior lineage A1 is placed in a P2 position can use either tip lineage 1 or 2 to represent it assuming no introgression has occurred into lineage 1 or 2. If introgression has occurred into lineage 1, then lineage 2 should be used to represent lineage A1 and introgression has occurred into lineage 2 then lineage 1 should be used to represent lineage A1. B) If introgression is supported from multiple P3 lineages that together make up a clade (e.g. lineages 1 to 3) into the same P2 or P1 lineage (e.g. lineage 4), then we assume the most parsimonious reconstruction of a single introgression event (shown by thick arrow) that involved the ancestral lineage preceding the clade of P3 species (e.g. lineage A2) rather than multiple introgression events (thin arrows). With this assumption it is possible to test for introgression involving many ancestral lineages. It is also possible to provide date ranges for introgression events. In the example in panel B, we can date the introgression event as having occurred after the node following lineage A3 at 6 Mya and before the node following lineage A2 at 5.5 Mya.

Figure 4. Maximum likelihood phylogeny estimated in IQ-Tree using 24,130 SNPs and 1,000 bootstrap replicates to indicate nodal support above branches. Tissue, field number or museum catalog number follows the taxon name.

Figure 5. Phylogenetic relationships among *Dendrocincla* taxa. Majority-rule consensus species tree from SVDQuartets using 24,130 SNPs. The numbers above the branches are non-parametric bootstrap values for nodal support which are shown only for nodes with less than 100% support. Ages of nodes were estimated using the multigene coalescent from the program G-PhoCS. Arrows denote significant gene flow events ($p < 0.005$) and point from the P3 species to the P1 or P2 species. The direction of the arrow does not imply introgression occurs in only this direction, though introgression from the P3 to the P1/P2 species is more likely (Martin et al. 2015). Circles show the nodes in which daughter lineages experienced introgression. Letters A to Q indicate internal branches also used in ABBA / BABA testing and referenced in Table 1 and S2.

Figure 6. The timing and magnitude of introgression events in *Dendrocincla* woodcreepers. A) Lineage age at hybridization (vertical bars indicate lower and upper estimates), time of hybridization (horizontal bars indicate lower and upper estimates). B) Relationship between the proportion of the genome introgressing (f_{hom}) and the lineage age at introgression (using the midpoint of the estimate). The black line in B shows the best fit exponential decay curve ($f_{\text{hom}} = 0.12 + 0.0045(1 - \exp(-t))$) fit to the midpoint estimates of lineage age at introgression. The black line in B shows the best fit linear relationship ($f_{\text{hom}} = 0.069 + 0.00027x$, where x = time of hybridization). Colours of introgression events correspond to those in Fig 5. The red dot represents *D. fuliginosa atrirostris* and *D. f. rufolivacea* which, despite currently possessing a hybrid zone, did not produce a significant ABBA/BABA test and whose f_{hom} was estimated to be less than 0.01.

Table S2. ABBA / BABA comparisons. *D* represents the *D* statistic and SE is the standard error. Z is the number of standard deviations from 0 (the expected value) for *D*. Significance was assessed for each replicate by converting the Z-score into a two tailed p-value, and using 0.005 as a conservative cutoff for significance. For species voucher information see Table S1.
