Abstract

The Abdominal Compartment Society (www.wsacs.org) previously created highly cited Consensus Definitions/Management Guidelines related to intra-abdominal hypertension (IAH) and abdominal compartment syndrome (ACS). Implicit in this previous work, was a commitment to regularly reassess and update in relation to evolving research. Two years preceding the Fifth World Congress on Abdominal Compartment Syndrome, an International Guidelines committee began preparation. An oversight/steering committee formulated key clinical questions regarding IAH/ACS based on polling of the Executive to redundancy, structured according to the Patient, Intervention, Comparator, and Outcome (PICO) format. Scientific consultations were obtained from Methodological GRADE experts and a series of educational teleconferences were conducted to educate scientific review teams from among the wsacs.org membership. Each team conducted systematic or structured reviews to identify relevant studies and prepared evidence summaries and draft Grades of Recommendation Assessment, Development and Evaluation (GRADE) recommendations. The evidence and draft recommendations were presented and debated in person over four days. Updated consensus definitions and management statements were derived using a modified Delphi method. A writing
committee subsequently compiled the results utilizing frequent Internet discussion and Delphi voting methods to compile a robust online Master Report and a concise peer-reviewed summarizing publication. A dedicated Paediatric Guidelines Subcommittee reviewed all recommendations and either accepted or revised them for appropriateness in children. Of the original 12 IAH/ACS definitions proposed in 2006, three (25%) were accepted unanimously, with four (33%) accepted by > 80%, and four (33%) accepted by > 50%, but required discussion to produce revised definitions. One (8%) was rejected by > 50%. In addition to previous 2006 definitions, the panel also defined the open abdomen, lateralization of the abdominal musculature, polycompartment syndrome, abdominal compliance, and suggested a refined open abdomen classification system. Recommendations were possible regarding intra-abdominal pressure (IAP) measurement, approach to sustained IAH, philosophy of protocolized IAP management and same-hospital-stay fascial closure, use of decompressive laparotomy, and negative pressure wound therapy. Consensus suggestions included use of non-invasive therapies for treating IAH/ACS, considering body position and IAP, damage control resuscitation, prophylactic open abdomen usage, and prudence in early biological mesh usage. No recommendations were made for the use of diuretics, albumin, renal replacement therapies, and utilizing abdominal perfusion pressure as a resuscitation-endpoint. Collaborating Methodological Guideline Development and Clinical Experts produced Consensus Definitions/Clinical Management statements encompassing the most contemporary evidence. Data summaries now exist for clinically relevant IAH/ACS questions, which will facilitate future scientific reanalysis.

Key words: intra-abdominal hypertension, abdominal compartment syndrome, critical care, grades of recommendation, assessment, development, and evaluation criteria, evidence-based medicine, abdominal compartment society

Anaesthesiology Intensive Therapy 2015, vol. 47, s63–s77

Owing to its restricted capacity to expand, the peritoneal cavity is subject to raised internal pressures like any other anatomic compartment. As pressure within this compartment increases above normal tissue perfusion pressure, the many critical viscera and vascular structures within may be compromised, initiating a cascade of events that may lead to organ dysfunction/failure and ultimately death, if not corrected. Thus, raised intra-abdominal pressure (IAP), which constitutes intra-abdominal hypertension (IAH), has been increasingly recognized as being common and associated with pathology when sought [1−5]. Detrimental physiologic associations with IAH have been recognized in nearly all organ systems, including the cardio-respiratory, renal, neurologic, gastrointestinal, hepatic, and adrenocortical systems; related both to physical and humoral effects, ultimately manifested as the abdominal compartment syndrome (ACS) if organ failure ensues [6−8]. Overt ACS is an end-stage manifestation of severe IAH, with a mortality approaching 100% without treatment in some reports [9]. As ACS represents organ failure from IAH, it may still be lethal, despite eventual decompression and correction of the underlying cause [10].

When first re-recognized in contemporary times, severe IAH/ACS was epidemic in severely ill/injured subgroups, such as those with massive intra-abdominal hemorrhage requiring damage control that had their abdomens closed primarily [11, 12]. Secondary ACS was seen in many patients, such as those with massive burns, or even extra-abdominal injuries in the setting of aggressive crystalloid resuscitation [13−15]. However, in the ensuing period of not more than two decades since Kron’s sentinel description of the syndrome and its treatment [9], there has been an exponential growth in attention, research, and published material related to both IAH and ACS [16, 17]. Specific milestones along this pathway included the incorporation of the World Society of the Abdominal Compartment Syndrome (WSACS — www.wsacs.org), its bi-annual scientific congresses, and a series of consensus guidelines relating to Definitions [18−20], Management [21], and Methods for Research [22], all produced by the WSACS. Although hard to directly attribute, the WSACS likely shares in the credit along with the United States Military, and Academic Institutions globally in heralding in a new era in resuscitation [23−27]. Concurrent major changes in the science and philosophy of the resuscitation and management of the critically injured/ill also include the wider application of damage control resuscitation for massive hemorrhage [25, 28−33], early goal directed therapy for severe sepsis [34], and an appreciation of the general risks of over hydration [35−37], all appear to have impacted the epidemiology and impact of IAH/ACS in these populations [38]. There have also been very significant paradigm shifts in the early delivery of care relating to both haemostatic and balanced resuscitation, such that it has been suggested that damage control itself may be less important than previously emphasized [39]. These changes are resulting in significant reductions in ACS [40].

The World Society of the Abdominal Compartment Syndrome has always prided itself in being a progressive and relevant organization. As much as success in addressing the most obvious catastrophic pathology of the ACS
has become apparent, it has become obvious that widespread understanding of the more complex role of IAH in multi-factorial critical illness/injury has not [41]. Thus, a notable scientific metamorphosis has been the rebranding of the World Society of the Abdominal Compartment Syndrome as the Abdominal Compartment Society, a society promoting cohesive approach to promoting research, fostering education, and improving the survival of patients with intra-abdominal hypertension (IAH) and/or abdominal compartment syndrome (ACS), as well as now embracing the surgery and science of reconstructing the abdominal compartment itself [42, 43]. There are two integral aspects to this rebranding. Firstly, there is a new holistic emphasis on including all clinicians, innovators and technicians, as well as pure scientists interested and involved in studying, manipulating and rehabilitating the abdominal compartment. Secondly, there is a desire to embrace the future while not forgetting the short but remarkable past accomplishments of the wsacs.org, thus providing the impetus to "abbreviate" the Abdominal Compartment Society as the wsacs.org.

In addition to rebranding however, as part of the more serious commitment of the wsacs.org to maintain the currency of its recommendations, the wsacs.org undertook a planned review and update of the previous Consensus Definitions and Management Guidelines to reflect recent advances in both clinical care and basic science [44]. Ambitiously, in order to uphold the highest standards regarding consistency in rating the quality of evidence and in communicating the level of confidence placed in the clinical practice guidelines, the principles of the Grading of Recommendations Assessment, Development and Evaluation (GRADE) system for clinical practice guidelines development were adhered to [45–51]. The results were a 200-page-plus resource document available on-line, with a high-level summary published in a highly ranked journal, namely Intensive Care Medicine, and supported by 44 drop-down menus each elaborating on the clinical definition/question of interest [52].

METHODS

GUIDELINES COMMITTEE COMPOSITION AND FUNCTION

The 2012 Guidelines Committee (GC) of the WSACS.org consisted of a Chair, Coordinator, two Methodological Advisors (impartial members of the GRADE Working Group), and eleven (11) systematic review teams. Among the non-methodological advisor GC members, eight were surgeons, who had subspecialty training in trauma and/or acute care surgery, general surgery, or vascular surgery, seven were experts in critical care medicine/anaesthesiology or internal medicine, while five practiced both surgery and critical care medicine. The goal was to provide an updated “state-of-the-art” reference for IAH/ACS-related clinical and basic science research, remembering that the existing definitions have previously been used to define IAH/ACS and related phenomena, wherein unnecessary changes would detract from the goal of diagnostic standardization and external validity.

EVALUATION OF EXISTING EXPERT CONSENSUS DEFINITIONS

The members reviewed, evaluated, and ultimately ratified the latest 2013 expert consensus definitions through ongoing discussion and debate through electronic mail messages and posts upon a dedicated electronic Expert Consensus Definitions Billboard. In concordance with the levels of agreement appropriate for consensus [48], all expert consensus definitions for which more than 80% of the members voted to accept “as is” were retained, while all with less than 50% acceptance were rejected. Definitions with only 50–80% agreement were revised through ongoing discussions until complete consensus was obtained. Where extensive discussion among subspecialists or other experts was required, special sub-committees were created, including a dedicated Paediatric Guidelines Sub-Committee which reviewed the adult guidelines regarding their generalizability to paediatrics and thereafter commented upon this when appropriate. Other special committees included special working groups which were set up to address the issues of abdominal compliance and the risk factors for IAH/ACS.

DEVELOPMENT OF CONSENSUS MANAGEMENT RECOMMENDATIONS

USE OF GRADE AND DEVELOPMENT OF CLINICAL QUESTIONS

We followed the GRADE approach for guideline developers to generate management recommendations related to IAH/ACS from the patient’s perspective [45]. Using this approach, GC members first defined specific clinical questions and patient-important outcomes with the assistance of two impartial methodological advisors and members of the GRADE Working Group (R.J., G.H.G.). Questions were formulated according to the Patient, Intervention, Comparator, and Outcome (PICO) format [53], and were based on polling of the WSACS Executive to redundancy concerning their interpretation of the most critical clinical questions in the realm of IAH/ACS. Redundancy means that the development of the questions continued until no new clinical question themes or ideas could be identified. The final 12 clinical questions were thus perceived to reflect the most important management issues facing clinicians and/or those for which the evidence had evolved most rapidly since the 2006 WSACS guidelines (Table 1). The GC then later refined these identified clinical questions of interest during a series of pre-meeting teleconferences with the assistance of the two methodological experts. The GC also reviewed the
Table 1. Most pertinent management questions concerning intra-abdominal hypertension and the abdominal compartment syndrome

1. **Should we measure IAP?** Does measuring intra-abdominal pressure (IAP) in critically ill or injured patients improve outcomes compared to strategies that do not consider or measure IAP?
2. **How should we treat/interpret IAP?** Does management strategy that use the abdominal perfusion pressure (APP) to guide management improve patient outcomes compared to strategies that do not consider the APP in critically ill adults with IAH (IAP > 12 mm Hg) in critical care units?
3. **Should we treat IAH/ACS?** Do overall management strategies attempting to keep standard-state IAP less than 20 mm Hg result in improved patients outcomes compared to management strategies (or the lack thereof) that either accept higher IAPs (or ignore IAP altogether) in critically ill adults in critical care units?
4. **How should we treat IAH/ACS non-operatively?** Do management strategies that use percutaneous drainage of intra-peritoneal fluid to reduce the IAP in cases of intra-abdominal hypertension improve patient outcomes compared to strategies that do not use percutaneous drainage in critically ill adults in critical care units?
5. **How should we treat IAH/ACS operatively?** Do management strategies that use decompressive laparotomy to reduce IAP in cases of overt abdominal compartment syndrome (ACS) improve patient outcomes compared to strategies that do not use decompressive laparotomy in critically ill adults in critical care units?
6. **With the ACS?**
   i. With grade III-IV ACS but no formal definition of the ACS?
   ii. With grade III-IV ACS but with a formal definition of the ACS?
7. **How should we avoid IAH/ACS? or how should we deal with the OA?** Does the use of a management strategy involving efforts at closing the fascia of an open abdomen (OA) improve patient outcomes compared to strategies that do not use strategies to close the fascia and which thus accept skin graft closures and delayed reconstruction in those critically ill adults with OAs in critical care units?
8. **How should we avoid IAH/ACS? or how should we deal with the OA?** Does the use of a management strategy involving efforts at closing the fascia of an open abdomen improve patient outcomes compared to strategies that do not use strategies to close the fascia and which thus accept skin graft closures and delayed reconstruction in those critically ill adults with OAs in critical care units?
9. **How should we avoid IAH/ACS? or how should we deal with the OA?** Does the use of a management strategy involving the early closure with bioprosthetic meshes improve patient outcomes compared to strategies that do not use bioprosthetic meshes and which thus accept skin graft closures and delayed reconstruction in critically ill adults with OAs in critical care units?
10. **How should we avoid IAH/ACS? or how should we deal with the OA?** Does the use of a management strategy involving component parts separation improve patient outcomes compared to strategies that do not use component parts separation in critically ill adults with OAs in critical care units?
11. **How should we avoid IAH/ACS?** Does a management strategy attempting to obtain fluid balance in equilibrium, or even a negative state (restrictive fluid strategy) after day 3, result in a lower IAP and improved patients outcomes compared to management strategies that either accept a liberal fluid management? Moreover, will use of a more liberal fluid strategy compared to a restrictive strategy the latter result in higher IAPs in critically ill adults in critical care units?
12. **How should we avoid IAH/ACS?** Does a massive transfusion strategy involving an enhanced ratio of plasma and/or minimizing crystalloid fluids result in a reduced incidence of IAH/ACS and related complications compared to strategies that do not?

WSACS Management Algorithm (Fig. 1) in light of recent developments.

**SYSTEMATIC REVIEWS**

Systematic review teams subsequently conducted systematic or structured/semi-structured reviews and prepared evidence profiles for each of the identified patient-important outcomes as suggested by GRADE [45, 54, 55]. As the details required to answer the Management question were potentially vast, each team was encouraged to prepare the detailed results as a stand-alone comprehensive review of this topic. To date, the systematic review of negative-pressure wound therapy (NPWT) comparative studies is the only one that has been individually prepared and published after peer review [56], while a systematic review on the deleterious effects of a positive cumulative fluid balance has partially been drafted [57].

**EDUCATING THE SYSTEMATIC REVIEW TEAMS**

Although the members of each systematic review team were clinical experts in IAH/ACS, with typically extensive experience in Research and Academia, they were not GRADE experts. Thus, in order to educate the teams, GRADE experts from the GRADE Working Group (R.J., G.H.G.) prepared instructional presentations that were hosted on the Guidelines Website for self-study and review. They also hosted two separate Web Seminar type presentations, both repeated at 12-hour time differences to allow for the different time zones that resulted from recruiting worldwide experts. Finally, basic GRADE and Methodological manuscripts were distributed for self-study.

**THE SCIENTIFIC EVIDENCE REVIEW AND EVIDENCE SUMMARY CREATION PROCESS**

Each Review team was led by a Chair, who was responsible for the conduct of the review, recruiting knowledgeable content experts who had engaged with the GRADE educational process, and for compiling an Evidence Summary and initial recommendations to the overall Committee.

**DELIBERATION AND DEVELOPMENT OF CONSENSUS MANAGEMENT RECOMMENDATIONS**

Formal face-to-face Expert Consensus Conference meetings for all GC members were held on two separate days immediately preceding and following the 5th Scientific Con-
Andrew W. Kirkpatrick et al., Updated WSACS consensus definitions

At the Management Guidelines meeting, each systematic review team presented their search methods and evidence profile to the GC and one of the methodological advisors (R.J.), whose role was to comment on their assessment of the quality of the available evidence. Each team then made recommendations to the Panel regarding the direction (for/against/no recommendation), strength (recommend/suggest), and confidence (on an ordinal scale of 1 to 3) of the recommendation in accordance with GRADE guidelines [45, 55, 58–61].

As recommended by GRADE, randomized controlled trials (RCTs) were considered to represent high-quality evidence and observational studies were considered low-quality evidence. Specifically, GRADE guidelines recommend that randomized controlled trials (RCTs) are considered to represent high-quality evidence, while observational studies are considered to provide lower-quality evidence.

Therefore, the updated definitions from the WSACS consensus meeting in Orlando, FL, U.S.A on August 10th to 13th, 2011, provide a comprehensive framework for the management of intra-abdominal hypertension and abdominal compartment syndrome (ACS), incorporating evidence from both RCTs and observational studies.

Figure 1. WSACS intra-abdominal hypertension, abdominal compartment syndrome management algorithm introduced in 2007.
quality evidence, unless modified downward due to risk of bias, imprecision, inconsistency of results, indirectness of evidence, or publication bias. Studies could also be modified upwards due to a large estimated magnitude of effect, evidence of a dose-response, or if confounders were likely to minimize the estimated magnitude of effect. Ultimately, the quality of evidence for each outcome was rated along a four-point ordinal scale in which each evidence grade was symbolized by a letter from D to A: very low (D), low (C), moderate (B), and high (A). Although principally designed for meta-analyses of RCTs, summary-of-findings tables were created whenever possible using GRADEpro version 3.2 and the format used by the American College of Chest Physicians. These tables presented estimates of relative effect as relative risks (RR), with their 95% confidence intervals and anticipated absolute effects as mean differences with their associated 95% confidence intervals. As meta-analyses of randomized trials or high quality observational studies were frequently unavailable, these estimates were often derived from those reported by a single study or across a number of studies. All statistical analyses were conducted using Stata version 12.0 (Stata Corp., College Station, TX, USA).

RESULTS

DEFINITIONS

The final accepted consensus definitions of the WSACS are presented in Table 2. Overall, the GC accepted three of the original 12 definitions unanimously, while one was rejected by more than 50% of the GC. Thus, four were originally accepted by > 80% of the GC, and four were accepted by greater than 50% of the GC, but required discussion to arrive at the presented definitions. The risk factors accepted in 2006 are shown in Table 3.

The subcommittee examining the basis for describing abdominal compliance was able to include its recommendations within the current report. The dedicated sub-committees of the GC tasked with examining the evidence-based risk factors for IAH and to discern the most relevant location for zeroing baseline IAP measurements, recognized the challenges and magnitude of these tasks, and were unable to
Polytransfusion (>10 units of packed red blood/24 hours)
Massive fluid resuscitation (>...)

Major trauma
Peritoneal dialysis
Sepsis (American — European Consensus Conference definitions)
Bacteraemia
Intra-abdominal infection/abscess
Peritonitis
Liver dysfunction/cirrhosis with ascites
Mechanical ventilation
Use of positive end expiratory pressure (PEEP) or the presence of auto-PEEP
Pneumonia
Abdominal surgery, especially with tight fascial closures
Massive fluid resuscitation (> 5 L of colloid or crystalloid 24 hours¹)
Gastroparesis/gastric distention/ileus
Volvulus
Haemoperitoneum/Pneumoperitoneum
Major burns
Major trauma
High body mass index (> 30 kg m²)
Intra-abdominal or retroperitoneal tumours
Prone positioning
Massive incisional hernia repair
Acute pancreatitis
Distended abdomen
Damage control laparotomy
Laparoscopy with excessive inflation pressures
Peritoneal dialysis

In order to facilitate research in this controversial field, the technical details regarding the type of temporary closure should be explicitly stated.

LATERALIZATION OF THE ABDOMINAL MUSCULATURE

There are many recognized complications of the open abdomen such as entero-atmospheric fistulae; heat, fluid, and protein losses; catabolism; and increased nursing resources; among many others. However, loss of domain, wherein the peritoneal contents no longer reside naturally within the confines of the abdominal wall, may be an overlooked concern. Although not well studied or reported, this phenomenon is increasingly being understood as both influencing the degree of complexity involved in abdominal wall reconstruction, and as an undesirable outcome that temporary abdominal closures (TAC) aim to avoid [64]. Thus, the WSACS defined lateralization of the abdominal wall to refer to the phenomenon whereby the musculature of the abdominal wall, most exemplified by the rectus abdominus muscles, moves laterally away from the midline with time and the pericolic gutters become obliterated [65].

CLASSIFICATION OF THE OPEN ABDOMEN

Planning to successfully and safely close any open abdomen must begin immediately after the abdomen is first left open. It is critical when studies are conducted that they address abdominal closure rates considering the indications for open abdominal management, differing comparators, and that abdominal-closure problems of similar difficulty are compared. Thus a classification scheme of open abdomen complexity is required. Two schemes have been previously proposed, that of Swan [66] and that of Bjorck [67]. The WSACS recognizes two critical complications which should be considered in managing an open abdomen; namely fixation of the abdominal contents, especially of the viscera to the side-walls, and the development of an entero-atmospheric fistula (EAF). The classification of Bjorck was therefore amended to reflect this hierarchy of challenges to the patient (Table 4).

POLYCOMPARTMENT SYNDROME

A polycompartment syndrome is a condition where two or more anatomical compartments have elevated compartmental pressures [68]. A compartment syndrome (CS) is defined as an increased pressure in a closed anatomic space which threatens the viability of enclosed and surrounding tissue [69]. Within the body there are 4 major compartments among many: the head, the chest, the abdomen and the extremities. Within each compartment, a CS can affect individual organs and can be associated with different causal disease states. The abdominal compartment has unique topographic properties because it is “up-stream” from the lower extremities and “down-stream” from the...

This is an update of the original Bjorck [67] classification. Enteric leak describes the situation where there is spillage of enteric contents into the abdomen without established enteric fistula development.

chest. Therefore, it may influence the pathophysiology of these compartments. Scalea et al. was the first to introduce the term multiple CS (MCS) in a study of 102 patients with increased IAP, intrathoracic (ITP), and intracranial pressure (ICP) after severe brain injury [70]. He suggested that different compartments within the body are not isolated and independent entities but instead are closely connected. Because the term multi or multiple CS is nowadays mostly used in relation to multiple limb trauma with CS needing fasciotomy, the term polycompartment syndrome (PCS) was finally coined in 2007 in order to avoid further confusion [71, 72]. Because of the clinical importance of diverse aspects of PCS, further classification in the future seems warranted. Firstly, PCS can either be primary or secondary or a combination of both, in view of the potential effect on organ function [73]. A primary CS is defined as a pathological rise of CP in a compartment due to physical tissue or organ injury within the compartment (i.e. intracranial haematoma or limb fracture). In secondary CS, there is no primary injury in the affected compartment and symptoms are solely based on pressure transmission from one compartment to another (i.e. ACS that develops following a tension pneumothorax) [74]. Different conditions precipitate the occurrence of PCS: severe burns, massive fluid resuscitation, severe sepsis, or prolonged hypotension.

ABDOMINAL COMPLIANCE

The abdominal compliance quantifies the ease of abdominal expansion and is determined by the elasticity of the anterior and lateral abdominal wall and, to a smaller degree, the diaphragm, whereas the more rigid spine and pelvis only minimally, if at all, affect abdominal elasticity [75–77]. The abdominal compliance changes with variations in abdominal volume. It can be expressed as the slope on a volume-pressure curve and this slope will depend on its position on the abdominal volume-pressure curve. In normal physiological conditions with normal abdominal volumes, an additional predefined abdominal volume will only minimally increase IAP. However, when the abdominal volume is already increased, as in high grade IAH, the same abdominal volume will significantly increase IAP. A reduced abdominal compliance implies that any change in volume increase will result in a greater change in IAP, as found in patients with abdominal burn eschar, tight closure following abdominal surgery, or generally in those with high grade of IAH. A compliant abdomen, however, indicates greater tolerance to changes in intra-abdominal volume as seen in elderly patients with loss of elastic recoil of the abdominal wall, women after childbirth or in the obese after weight loss. Abdominal compliance should be expressed in L mm Hg⁻¹. Thus, the WSCAS defined “abdominal compliance” as a measure of the ease of abdominal expansion, determined by the elasticity of the abdominal wall and diaphragm and is expressed as a change in intra-abdominal pressure per change in intra-abdominal volume [78, 79]. The respiratory changes between end-inspiratory and end-expiratory IAP that can be observed in the IAP tracing are an indirect surrogate marker of abdominal wall compliance [75, 80].

PAEDIATRIC GUIDELINES SUB-COMMITTEE

Akin to the adult situation, the influences of IAH and the occurrence of ACS is being more commonly reported in children [81]. While the original, and now the revised WSACS guidelines may serve as guides for many conditions, they cannot be applied directly to all children [81–83]. The Paediatrics Sub-Committee reviewed these guidelines derived from adult care and considered their applicability for use in paediatrics. The Sub-Committee accepted 10 of the adult definitions as appropriate for paediatric use, rejected 4 as inappropriate and was unable to make a recommendation regarding appropriateness concerning the threshold levels of IAH grades (not to be confused with the GRADE methodology). The sub-committee also reviewed relevant paediatric studies to arrive at the accepted and proposed paediatric definition [44].

A summary of the final accepted Paediatric Definitions is presented in Table 5. For the four definitions rejected, new definitions, specific for paediatric use were proposed. As the threshold cut-off of 20 mm Hg may be too high in certain patients and as APP thresholds of 60mm Hg were definitely considered too high, the Paediatric Sub-Committee of the WSACS defines ACS in children as a sustained elevation in IAP of greater than 10 mm Hg associated with new or worsening organ dysfunction that can be attributed to elevated IAP. Several studies have demonstrated that over-distending the bladder with a priming volume of fluid may lead to
Table 5. Final 2013 Adapted Paediatric Consensus Definitions

Definitions Accepted Without Change from the Adult Guidelines
1. Intra-abdominal pressure (IAP) is the steady-state pressure concealed within the abdominal cavity
2. Abdominal perfusion pressure (APP) = Mean arterial pressure (MAP) minus IAP
3. Primary ACS is a condition associated with injury or disease in the abdomino-pelvic region that frequently requires early surgical or interventional radiological
4. Secondary ACS refers to conditions that do not originate from the abdomino-pelvic region
5. IAP should be expressed in mm Hg and measured at end-expiration in the complete supine position after ensuring that abdominal muscle contractions are absent and with the transducer zeroed at the level of the mid-axillary line
6. Recurrent ACS refers to the condition in which ACS redevelops following previous surgical or medical treatment of primary or secondary ACS
7. The polycompartment syndrome is a condition where 2 or more compartments have elevated compartment pressures
8. An Open Abdomen is one in which the abdominal viscera are exposed to the outside environment or retained by a non-autologous artificial barrier which should be explicitly described
9. Pathophysiological Classification of the Open Abdomen
   1A: clean, no fixation
   1B: contaminated, no fixation
   1C: enteric leak, no fixation
   2A: clean, developing fixation
   2B: contaminated, developing fixation
   2C: entero-atmospheric/cutaneous fistula, developing fixation
   3: frozen abdomen, no fistula
   4: frozen abdomen with entero-atmospheric/cutaneous fistula
   This allows recognition of the significant increase in morbidity and mortality in the presence of an enteric leak/fistula in the lower grades while maintaining sufficient similarity to the original classification system in order that a comparison with previous studies could be possible
10. Abdominal wall compliance defines a concept regarding the ease of expansion of the abdominal wall and its contents which is determined by the overall intra-abdominal volume and elasticity of the abdominal wall

Proposed Paediatric Specific Definitions
1. ACS in children is defined as a sustained elevation in IAP of greater than 10 mm Hg associated with new or worsening organ dysfunction that can be attributed to elevated IAP
2. The reference standard for intermittent IAP measurement in children is via the bladder using 1 mL kg⁻¹ with a minimal instillation volume of 3 mL and a maximum instillation volume of 25 mL of sterile saline
3. Normal IAP in critically ill children is approximately 4–10 mm Hg
4. IAH in children is defined by a sustained or repeated pathological elevation in IAP > 10 mm Hg

Although the data is limited in quality, it is well known that all physiologic pressures are generally lower in children than in adults, including IAP, even during critical illness [83].

CONSENSUS MANAGEMENT STATEMENTS
The PICO structured questions are presented in Table 6. The final accepted Consensus Management Statements are summarized in Table 7 and Figure 2, while a further in-depth discussion may be accessed via the online supplemental material accompanying the 2013 revised consensus definitions and management guidelines [44]. Table 8 lists the opinions of the Paediatric Care Sub-Committee Regarding the suitability of the WSACS Management Recommendations for the care of children. In each source document, each clinical question has been presented with a format that includes an overview of the background (narrative), evidence summary,

</tbody>
</table>

Where ACS indicates abdominal compartment syndrome; APP — abdominal perfusion pressure; IAH — intra-abdominal hypertension; IAP — intra-abdominal pressure; ICU — intensive care unit; KCI — Kinetic Concepts Incorporated; NPT — negative pressure therapy; NPWT — negative pressure wound therapy; RCTs — randomized controlled trials; VAC — vacuum-assisted closure.
Table 7. Final 2013 WSACS.org Consensus Management Statements

**Recommendations**

1. We recommend measuring IAP when any known risk factor for IAH/ACS is present in a critically ill or injured patient [GRADE 1C]
2. Studies should adopt the trans-bladder technique as the standard IAP measurement technique [not graded]
3. We recommend use of protocolized monitoring and management of IAP versus not [GRADE 1C]
4. We recommend efforts and/or protocols to avoid sustained IAH among critically ill or injured patients [GRADE 1C]
5. We recommend decompressive laparotomy in cases of overt ACS compared to strategies that do not use decompressive laparotomy in critically ill adults with ACS [GRADE 1D]
6. We recommend that among ICU patients with open abdominal wounds, conscious and/or protocolized efforts be made to obtain an early or at least same hospital stay abdominal fascial closure [GRADE 1D]
7. We recommend that among critically ill/injured patients with open abdominal wounds, strategies utilizing negative pressure wound therapy should be used versus those that do not [GRADE 1C]

**Suggestions**

1. We suggest that critically ill or injured patients receive optimal pain and anxiety relief [GRADE 2D]
2. We suggest brief trials of neuromuscular blockade as a temporizing measure in the treatment of IAH [GRADE 2D]
3. We suggest that the potential contribution of body position to elevated IAP be considered among patients with, or at risk of, IAH or ACS [GRADE 2D]
4. We suggest using a protocol to try and avoid a positive cumulative fluid balance in the critically ill or injured patient with, or at risk of, IAH after the acute resuscitation has been completed and the inciting issues/source control have been addressed [GRADE 2C]
5. We suggest the use of PCD to remove fluid (in the setting of obvious intraperitoneal fluid) in those with IAH/ACS when this is technically possible compared to doing nothing [GRADE 2C]. We also suggest using PCD to remove fluid (in the setting of obvious intraperitoneal fluid) in those with IAH/ACS when this is technically possible compared to immediate decompressive laparotomy, as this may alleviate the need for decompressive laparotomy [GRADE 2D]
6. We suggest brief trials of neuromuscular blockade as a temporizing measure in the treatment of IAH [GRADE 2D]
7. We suggest that patients undergoing laparotomy for trauma suffering from physiologic exhaustion be treated with the prophylactic use of the open abdomen versus intraoperative abdominal fascial closure and expectant IAP management [GRADE 2D]
8. We suggest not routine utilizing the open abdomen for patients with severe intraperitoneal contamination undergoing emergency laparotomy for intra-abdominal sepsis unless IAH is a specific concern [GRADE 2B]
9. We suggest that bioprosthetic meshes should not be routinely used in the early closure of the open abdomen compared to alternative strategies [GRADE 2D]

**No Recommendations**

1. We could make no recommendation regarding use of abdominal perfusion pressure in the resuscitation/management of the critically ill/injured
2. We could make no recommendation regarding use of diuretics to mobilize fluids in hemodynamically stable patients with IAH after the acute resuscitation has been completed and the inciting issues/source control have been addressed
3. We could make no recommendation regarding the use of renal replacement therapies to mobilize fluid in hemodynamically stable patients with IAH after the acute resuscitation has been completed and the inciting issues/source control have been addressed
4. We could make no recommendation regarding the administration of albumin versus not doing so to mobilize fluid in hemodynamically stable patients with IAH after the acute resuscitation has been completed and the inciting issues/source control have been addressed
5. We could make no recommendation regarding the prophylactic use of the open abdomen in non-trauma acute care surgery patients with physiologic exhaustion versus closing and expectant IAP management
6. We could make no recommendation regarding use of an acute component separation technique versus not doing so, in order to facilitate earlier abdominal fascial closure

ACS — abdominal compartment syndrome; IAP — intra-abdominal pressure; IAH — intra-abdominal hypertension; PCD — percutaneous catheter drainage

Andrew W. Kirkpatrick et al., Updated WSACS consensus definitions

Presentation structure previously employed by the American College of Chest Physicians. The consensus management statements currently represent the most thoughtful analysis of the available data and consideration of patient and societal factors that could be made by the Voting panel of the WSACS. Overall, the evidence was generally weak, and represented a “call to arms” to all clinician/scientists in order to attempt to improve the evidence base to allow more informed bedside management. This presents one of the great strengths of the GRADE methodology which, while typically associated with the analysis of high-level scientific evidence [51, 88, 89], is also equally applicable to important clinical questions in which the evidence base is not robust [50].
DISCUSSION AND CONCLUSIONS

As a result of this rigorous but somewhat complex process, the Abdominal Compartment Society (WSACS.org) was able to present updated consensus definitions and recommendations relevant for IAH/ACS in the second decade of the 21st Century [52]. However, the Abdominal Compartment Society is aware that there are continuous developments in medical knowledge and that much scientific study continues worldwide in all disciplines in general, as well focusing on IAH/ACS specifically. Another great benefit of utilizing the GRADE methodological approach is that dedicated scientific review panels have produced meticulous evidence profiles that now constitute a WSACS Resource that may be augmented and reanalysed at regular future
portunities regarding IAH/ACS research and has delegated the WSACS.org Research Committee to begin to address the most critical questions. Thus, the WSACS.org hopes to leverage this critical analysis which has been vital to the existing database and to commission critical research in order to better the care of our most critically ill/injured patients.

ACKNOWLEDGEMENTS

1. We thank Gordon Guyatt, MD, MSc, Department of Medicine, McMaster University, Hamilton, Ontario, Canada L8P 3B6, Department of Clinical Epidemiology and Biostatistics, McMaster University for Methodological guidance. We also thank Ms. Michelle Mercado and Ms. Alma Rados of the Trauma Association of Canada for webhosting and editing.

2. This manuscript was commissioned and supported by the abdominal compartment society (www.wsacs.org).

3. Andrew W. Kirkpatrick: Has served on an Advisory Board for Lantheus Medical, Boston, MA, discussing the use of ultrasound contrast media. He has also received an unrestricted research grant from Kinetic Concepts Incorporated to conduct a prospective randomized trial in open abdomen management. He also received the unrestricted use of a Sonosite NanoMaxx ultrasound machine for research use from the Sonosite Corporation. Jan DeWaele: has consulted for the Smith and Nephew, Kinetic Concepts, Pfizer and Astra Zenica Corporations. Roman Jaeschke: served as a consultant on behalf of the GRADE group to the World Society of the Abdominal Compartment Syndrome Manu L.N.G. Malbrain: Is member of the Medical Advisory Board of Pulsion Medical Systems (Maquet Getinge Group), and has consulted for Convatec, KCI and Fresenius-Kabi. Martin Bjorck: Received an unrestricted research grant from Kinetic Concepts Incorporated in 2009 and from Smith and Nephew Ltd. in 2010–2011. Michael Cheatham: has consulted for the Kinetic Concepts Incorporated Corporation and has provided expert legal testimony concerning intra-abdominal hypertension and the abdominal compartment syndrome. Rao Ivatury: has consulted for the Kinetic Concepts Incorporated Corporation. Annika Reintam Blaser: has consulted for Nestle Health Science. Mark Kaplan: served as a consultant for the Kinetic Concepts Incorporated Corporation. The other authors declare no conflict of interest.
