An anionic phosphenium complex as an ambident nucleophile†

B. Stadelmann, a J. Bender, a D. Förster, a W. Frey, b M. Nieger c and D. Gudat* a

A unique anionic phosphenium complex was prepared from reaction of an N-heterocyclic chlorophosphate with Collman's reagent or K[Fe(CO)4]/NaH and characterized by spectral and XRD data. The complex behaves as an ambident nucleophile. Reactions with acetic acid, C6H5PPh3, and a further equivalent of an N-heterocyclic chlorophosphate proceed via electrophilic functionalization at the metal site to yield appropriate mono- or bis-phosphenium complexes. Reaction with Mel at −70 °C produces a P-alkylation product as the first spectroscopically detectable intermediate, which decays at a higher temperature to give a mixture of free P-methylated N-heterocyclic phosphine and its Fe(CO)4 complex. The different reaction products were characterized by spectral and XRD data. Computational studies indicate that the NHP units in all complexes display π-acceptor behaviour but show no disposition to adopt phosphide-like character or formally oxidize the metal centre.

Introduction

Cyclic diaminophosphonium ions (Ia, Scheme 1) are isosteric analogues of N-heterocyclic carbenes (NHCs, Ib) and, like NHCs, form a large variety of transition metal complexes.1 However, whereas NHCs are nucleophiles and act mainly as strong σ-donor ligands, N-heterocyclic phosphonium ions (NHPs) are ambiphiles that combine a strong (π-)acceptor power with limited (σ-)donor ability, and interact with electron poor metal fragments to form a main dative M → L σ-bond and a weaker dative L → M σ-bond.1,2 This bonding situation compares to that in metal carboxyls or Fischer-type (electrophilic) carbene complexes,1r,2 and the M–P-bonds exhibit accordingly distinct double bond character (cf. IIa, Scheme 1). In complexes with electron rich and weak Lewis acidic metal fragments, NHPs can also act as electrophiles3 (“Z-type ligands”) that have been considered to bind essentially via a dative M → P bond (cf. IIb, Scheme 1).5 It has recently been pointed out that the bonding in complexes of this type may be portrayed as the interaction of an anionic (“X-type”) phosphido ligand with a formally oxidized metal centre, and that the dualism of both descriptions together with the pyramidalization at the phosphorus atom and M–P bond lengthening upon transition from IIA to IIb allows one to draw parallels to the “non-innocent” behaviour of metal nitrosyls.6

The unique disposition of NHPs to interact with low valent metal centres has repeatedly been used to stabilise anionic metal fragments [M(L)nX]− (containing usually a zero-valent metal atom and an anionic ligand X)h so that to date both cationic ([[(NHP)M(L)n]]+) and neutral NHP complexes ([(NHP)M(L)nX]) are known.1–8 Although the chemistry of the latter has not been widely explored, they are expected to display a similar distributed nucleophilicity as neutral complexes of acyclic aminophosphonium ions which can be attacked by electrophiles at the metal atom, the phosphorus atom, or the MP bond, respectively.9

In the light of these findings, complexes [[(NHP)M(L)n]−] with an overall negative charge and CC-unsaturated NHP ligands (1,3,2-diazaphospholenium ions) make an interesting synthetic target. These specimens should be accessible from suitable phosphorus electrophiles and metallate dianions featuring a metal atom in the negative formal oxidation state. Coordinated diazaphospholenium ions, apart from providing...
tunable steric protection, exhibit low tendency toward “non-innocent” behaviour,7b and should thus provide electronic stabilization without entirely removing the electron excess at the metal atom. The formed complexes might then still behave as metal-centred nucleophiles, a class of compounds that has lately gained attention for uses in catalysis.10

Following these lines, we report here on the synthesis of a NHP carboxyl ferrate, which is a first anion analogue of cationic and neutral phosphonium complexes, and on initial reactivity studies, which confirm that this species behaves in fact as a metal-centred nucleophile but retains also some ambident character.

Results and discussion

By analogy to the known synthesis of neutral phosphonium tricarbonylcobalates,5 2-chloro-1,3,2-diazaphospholene 1 reacted with Collman’s reagent Na2[Fe(CO)5] via salt elimination and decarbonylation to afford the anionic NHP complex [[NHP\textsubscript{OPP}]\textsuperscript{−} Fe(CO)\textsubscript{3}] (2; [NHP\textsubscript{OPP}] = 1,3-di-(2,6-di-isopropylphenyl)-1,3,2-diazaphospholium, Scheme 2).

A crude product of composition Na[2] was isolated as a brown-red, highly air and moisture sensitive solid after separation of NaCl and evaporation of the solvent. Crystalline [PPh\textsubscript{4}][2] was isolated after anion exchange with [PPh\textsubscript{4}]Cl. Both products were readily identified by spectral data and a single-crystal XRD study of [PPh\textsubscript{4}][2] (Fig. 1). The orthorhombic crystals (space group Pna2\textsubscript{1}, no. 33) contain two crystallographically independent pairs of isolated Ph\textsubscript{4}P\textsuperscript{−} and [[NHP\textsubscript{OPP}]\textsuperscript{−}Fe(CO)\textsubscript{3}]\textsuperscript{−} ions with similar metric parameters. The distorted tetrahedral and trigonal planar (sum of bond angles 360.0(5)°) coordination at the iron and phosphorus atoms and the bond lengths in the planar NHP-rings of the anion (see Fig. 1) are similar as in the isosteric complexes [[NHP\textsubscript{OP}](Co(CO)\textsubscript{5})\textsuperscript{−}](R = Ph)\textsuperscript{5},7 and indicate that the NHP unit acts as an ambiphilic σ-donor/π-acceptor rather than the pure Z-type ligand. In order to validate this hypothesis by DFT calculations (B3LYP/def2-tzvp with inclusion of solvent effects using a polarizable continuum model; see Experimental for details), we performed a geometrical optimization and ensuing NBO calculation\textsuperscript{20} on the model anion [[NHP\textsubscript{OPP}]Fe(CO)\textsubscript{3}]\textsuperscript{−} (2′). The computed molecular structure replicates all important structural features of 2, including in particular the planar coordination at phosphorus and short P-Fe bond length (2.006 Å). Inspection of KS orbitals (see ESI\textsuperscript{†}) and Wiberg Bond Indexes (WBI) confirms that the Fe-P bond receives a strong covalent contribution from a combination of dative σ- and π-bonding interactions, and has thus

![Fig. 1 Representation of the molecular structure of one crystallographically independent ion pair in [PPh\textsubscript{4}][2]. H-atoms were omitted for clarity. Selected bond lengths [Å] (numbers in brackets refer to the second crystallographically independent unit: Fe1–C31 1.762(5) [1.768(5)], Fe1–C32 1.768(5) [1.750(6)], Fe1–C33 1.758(6) [1.754(5)], Fe1–P1 1.989(1) [1.989(2)], P1–N5 1.689(4) [1.703(4)], P1–N2 1.712(4) [1.710(4)], N2–C3 1.380(6) [1.399(6)], C3–C4 1.357(6) [1.333(7)], C4–N5 1.408(6) [1.416(6)].]

Scheme 2  \( R = \text{Dipp}; \) conditions: (i) 1 equiv. Na2[Fe(CO)5], THF, –78°C, 2 h; (ii) 1 equiv. Ph4PCL, THF; (iii) 1 equiv. KH[Fe(CO)5], –78°C → r.t., 2 h; (iv) CH3CO2H/CH3CO2D, r.t.; (v) 1 equiv. NaH, 0 °C, 12 h; (vi) 1 equiv. Ph3SnCl, r.t., 5 min.

![Image]
notable double bond character (WBI 1.41 vs. 1.35 for the Fe–C bonds). The overall natural charge of the coordinated NHP unit (+0.86) is lower than in the free ligand, indicating that the NHP plays a part in delocalizing the negative charge on the carbonyl ferrate moiety but retains its electrophilic character. The large opposite charges on the iron (~2.41) and phosphorus atoms (+1.52) suggest that the metal–ligand bond also has a strong electrostatic component. The population analyses indicate that, regardless of any superficial analogies, the behaviour of the NHP moiety in 2/2′ differs markedly from that of the strongly reduced nitrosyl unit in [Fe(CO)3(NO)]+. Considering that such a charge distribution should support a behaviour as an iron-centred nuclophilic, we studied reactions of Na[2] with various electrophiles. Treatment with acetic acid gave iron hydrido complex 3a (Scheme 1) which was identified by the observation of mutually coupled (2JH=88 Hz) NMR signals for a metal bound H-atom (δH=−8.88) and the phosphorus atom of a phosphonium ligand (δ31P=225.0). The reaction of Na[2] with deuterated acetic acid gave appropriately 3b. Complex 3a is also directly accessible from 1 and K[HFe(CO)4] which reacts below ambient temperature under metathesis and decarbonylation (Scheme 2). This conversion contrasts known reactions of chlorophosphines, which undergo transfer of the hydride to the phosphorus atom and yield phosphine complexes. A single-crystal XRD study revealed that the iron atom in 3a exhibits trigonal bipyramidal coordination and the H- and NHP-ligands occupy axial and equatorial positions, respectively (Fig. 2).

The protonation of 2 to 3a can be reversed by the action of a strong base (NaH), and combining the reaction of K[HFe(CO)4] and 1 with a subsequent deprotonation offers thus alternative access to anion 2. Monitoring the deprotonation of 3a by 31P NMR allowed us to establish that the reaction is slow and 2 and 3a undergo no dynamic exchange on the NMR time scale, indicating that the kinetic acidity of 3a is unusually low. Reaction of Na[2] with ClSnPh3, which is a softer electrophile than H+, proceeds likewise under attack at the metal to afford complex 4 (Scheme 2) which was identified by spectral data and a single-crystal XRD study (see ESIF). The iron atom adopts trigonal-bipyramidal coordination like in 3a, but the Ph3Sn and NHP ligands occupy now both axial positions, presumably due to steric reasons.

Electrophilic attack at iron is also observed upon treatment of Na[2] with one more equivalent of 1. The reaction proceeds with spontaneous decarbonylation to yield bis-NHP complex 5 (Scheme 3) which is a rare example of a complex featuring two terminal phosphonium ligands coordinated to the same metal atom. A single-crystal XRD study (Fig. 3) reveals distorted tetrahedral coordination at iron, whereas the Fe–C and Fe–P bond lengths and the trigonal planar coordination at the phosphorus atoms are similar as in 2–4.

Computational studies on model complexes 3a′/5′ (with NMe instead of NDipp residues) imply a slight weakening of Fe–P bonds (Fe–P 2.047/2.017 Å; WBI 1.20/1.33) compared to 2′, which is mainly because of the M → L π-bonding and creates an enlarged partial charge (1.01/1.19) on the NHP unit. These findings confirm the role of the phosphonium moieties as Fischer-carbene analogue ligands which exert their stabilizing influence by a combination of amphiphilic σ-donor/π-acceptor and electrostatic interactions. A marked π-acceptor character of the NHP unit is once more highlighted by the
large blue shift of the \( \nu \text{CO} \) modes of \( 3a \) (2014, 1960, 1933 cm\(^{-1}\)) and \( 4 \) (2064, 1978, 1909 cm\(^{-1}\)) in comparison with analogous phosphate complexes like \([\text{HFe(CO)}_3\{\text{P(OME)}_3\}]^+ \) (a, \( a' \)- and e-modes at 1941 and 1841 cm\(^{-1}\) [ref. 15b]) and \([\text{Ph}_2\text{SnFe(CO)}_3\{\text{P(OME)}_3\}]^+ \) (a, \( a' \)- and e-modes at 1925 and 1820 cm\(^{-1}\) [ref. 19]), respectively. On the other hand, the observation of higher \( \nu \text{CO} \) frequencies in \([\text{Fe(CO)}_5\{\text{NO}\}]^{25} \) (2092, 2046 cm\(^{-1}\)) seems appealing as it may carry weakly bound solvent ligands.

In conclusion, we describe the successful synthesis of a NHP carbonyl ferrate which complements known cationic and neutral phosphonium complexes by a first anionic derivative. Structural and computational studies indicate that the ligand retains its electrophilic nature and shows no disposition to adopt phosphide-like character or formally oxidize the metal centre. Accordingly, the NHP ferrate reacts mainly as a metal centred nucleophile, but still retains some of the ambident character that is otherwise typical of neutral metallophosphonium complexes.

### Experimental

#### General conditions

All manipulations were carried out under dry argon. Solvents were dried by standard procedures. NMR spectra were recorded on Bruker Avance AV 400 or AV 250 instruments (\( ^1\text{H} \): 400.1/250.0 MHz, \( ^{13}\text{C} \): 100.5/62.9 MHz, \( ^{31}\text{P} \): 161.9/101.2 MHz); chemical shifts were referenced to ext. TMS (\( ^1\text{H} \), \( ^{13}\text{C} \)), 85% Fe–CH\(_3\) units, but come close to those of the P-bound substituents in \( 6 \) (\( \delta^{1}\text{H} = 1.96, \delta^{13}\text{C} = 29.5 \)), gives a first indication that the methyl is bound, like in \( 6 \) and \( 7 \), to the phosphorus rather than the iron atom. This assignment is further supported by (i) the presence of two distinguishable anisochronous environments for the iPr-groups in the NDipp-substituents, which implies that the coordination at phosphorus is pyramidal or tetrahedral (as in \( 6 \) and \( 7 \)) rather than planar (as in \( 2-5 \)), and (ii) the observation of \( ^1\text{H}-\text{NOESY} \) cross peaks which connect the CH\(_3\)-signal with both the signal of the CH-atoms in the diazaphospholene ring and the signals of one anisochronous iPr-group (the one on the same side of the five-membered ring; see ESI†). On this basis, we formulate the product as a complex in which the iron atom is bound to three carbylons and the neutral phosphine \( 7 \), and the remaining coordination site remains empty or is occupied by a solvent molecule \( 8 \), Scheme 3). Starting from this assignment, the conversion of \( 8 \) into a mixture of \( 6 \) and \( 7 \) is explained as the consequence of ligand extrusion/redistribution reactions which are common for carbonyl complexes that are coordinatively unsaturated or carry weakly bound solvent ligands.

Considering that the VT NMR studies provided no evidence for the formation of a metal functionalized species as a precursor to \( 8 \), we consider it likely that this species may indeed constitute the initial reaction product. Even if this interpretation seems at first glance counterintuitive, it is backed by the finding that the HOMO–1 of \( 2' \) (which arises from mixing a filled metal-centred orbital with a \( \sigma^*(\text{PN}) \) ligand orbital) contains a perceptible P-centred contribution, and the anion retains thus a certain degree of ambident character. It is currently under investigation if the attack of carbon-based electrophiles can be directed by steric effects.
H₂PO₄ (ε = 40.840747 MHz, ³¹P). FT-IR spectra were recorded on a Thermo Scientific Nicolet iS5 instrument equipped with an iD5 ATR accessory. Elemental analyses were carried out using an Elementar Micro Cube. Melting points were determined with a Büchi B-545 melting point apparatus in sealed capillaries. Collman’s reagent was prepared as described elsewhere.²⁷

Syntheses

Na₂[Fe(CO)₄]: (a) A solution of Na₂[Fe(CO)₄] (390 mg, 1.12 mmol) in THF (20 ml) was cooled in a dry ice/acetone bath to −78 °C. A solution of 1 (500 mg, 1.12 mmol) in THF (5 ml) was added dropwise. The solution was allowed to warm to r.t., stirred for 2 h, and filtered. The filtrate was concentrated to a volume of approx. 5 ml. Addition of hexane (15 ml) produced a brown-red precipitate which was filtered off, washed with additional hexane, and dried under vacuum to give 312 mg (48%) of a brown-red, air and moisture sensitive solid, m.p. 306 °C (dec.).

(b) Solid NaH (8.7 mg, 0.37 mmol) was added to a solution of complex 3 (200 mg, 365 μmol) in THF (10 ml THF). The mixture was stirred overnight. The solution was filtered to remove undissolved NaH. The solvent was removed under reduced pressure. The remaining solid was washed with hexane and dried under vacuum to give 141 mg (67%) of a brown-red, air and moisture sensitive solid, m.p. 306 °C (dec.).

Solid [Ph₄P]Cl (137 mg, 365 μmol) was added with stirring. The resulting mixture was filtered to remove precipitated NaCl. The filtrate was evaporated to dryness. The residue was dissolved in a minimum amount of THF. Storing the solution at 4 °C gave 230 mg (71%) of orange crystals, m.p. >350 °C (dec.).

Na₂[Fe(CO)₄]: A solution of Na₂[Fe(CO)₄] (390 mg, 1.12 mmol) in THF (20 ml) was cooled in a dry ice/acetone bath to −78 °C. A solution of 1 (500 mg, 1.12 mmol) in THF (5 ml) was added dropwise. The solution was allowed to warm to r.t. and stirred for another 2 h. The solvent was removed under reduced pressure. The remaining black solid was extracted with hexane. The mixture was filtered and evaporated to dryness. The residue was dissolved in a minimum amount of hexane. The resulting solution was stored at 4 °C to give 573 mg (93%) of 3a as yellow crystals, m.p. >350 °C (dec.).

(a) A solution of Na₂[Fe(CO)₄] (390 mg, 1.12 mmol) in THF (20 ml) was cooled in a dry ice/acetone bath, and a solution of 1 (500 mg, 1.12 mmol) in THF (5 ml) was added dropwise. The solution was allowed to warm to r.t. and stirred for another 2 h. The solvent was removed under reduced pressure. The remaining black solid was extracted with hexane. The mixture was filtered and evaporated to dryness. The residue was dissolved in a minimum amount of hexane. The resulting solution was stored at 4 °C to give 573 mg (93%) of 3a as yellow crystals, m.p. >350 °C (dec.).

(b) A solution of Na₂[Fe(CO)₄] (390 mg, 1.12 mmol) in THF-d₄ was treated with a drop of glacial acetic acid or acetic acid-d₄. The formed products (3a, b) were identified by their NMR data.

3a: ³¹P{¹H} NMR (CD₂Cl₂): δ = 225.0 (s). ¹H NMR (CD₂Cl₂): δ = 7.18 (m, 6 H, C₆H₅), 6.13 (d, 2 H, JPH = 6.7 Hz, =CH), 3.07 (sept, 4 H, JHH = 6.9 Hz, CH(CH₃)₂), 1.36 (d, 12 H, JPH = 6.9 Hz, CH(CH₃)₂), 1.10 (d, 12 H, JHH = 6.9 Hz, CH(CH₃)₂), -0.88 (d, 1 H, JpH = 88.1 Hz, FeH). ¹³C{¹H} NMR (CD₂Cl₂): δ = 214.30 (d, JPC = 13.6 Hz, CO), 147.0 (d, JPC = 3.0 Hz, o-C), 132.9 (d, JPC = 5.9 Hz, i-C), 130.2 (d, JPC = 1.4 Hz, p-C), 124.4 (d, JPC = 1.0 Hz, m-C), 123.6 (d, JPC = 1.7 Hz, =CH), 28.9 (s, C(CH₃)₂), 24.4 (s, CH₃), 23.0 (s, CH₃). IR: v = 2014, 1960, 1933 cm⁻¹ (iCO). Elemental analysis: calcd for C₉H₉Fe₂N₂O₂P: C 63.51, H 6.80, N 5.11; found C 63.06, H 6.86, N 5.09.

3b: ³¹P{¹H} NMR (d₈-THF): δ = 228.1 (s), JPC = 13.5 Hz. ¹H NMR (d₈-THF): δ = 7.36 (m, 2 H, C₆H₅), 7.24 (m, 4 H, C₆H₅), 6.88 (d, 2 H, JPH = 6.8 Hz, =CH), 2.89 (sept, 4 H, CH(CH₃)₂), JHH = 6.8 Hz, 1.19 (d, 12 H, CH(CH₃)₂), JHH = 6.8 Hz, 1.11 (d, 12 H, CH(CH₃)₂), JHH = 6.8 Hz).

4: A solution of Na₂[Fe(CO)₄] was prepared by dissolving complex 3a (30 mg, 54 μmol) in THF-d₈ and deprotonating with NaN₃ (1.3 mg, 54 μmol). After quantitative conversion had been established by NMR spectroscopy, triphenyltin chloride (20 mg, 54 μmol) was added. After 5 min, the reaction was complete, and precipitated solids were removed via decantation. After the evaporation of d₇-THF, the product was isolated as red crystals, yield 47 mg (93%), m.p. >350 °C (dec.).

³¹P{¹H} NMR (d₇-THF): δ = 251.2 (s, J₁H₁₉=11750P = 220/211 Hz). ¹H NMR (d₇-THF): δ = 7.45–7.05 (m, 23 H, C₆H₅C₆H₅ and =CHH), 1.33 (sept, 4 H, JHH = 6.8 Hz, CH(CH₃)₂), 1.24 (d, 6 H, JHH = 6.8 Hz, CH(CH₃)₂), 1.23 (d, 6 H, JHH = 6.8 Hz, CH(CH₃)₂), 1.3 (d, 7, JPC = 4.1 Hz, o-C), 137.0 (s, o-C), 133.4 (d, JPC = 5.4 Hz, o-C), 130.5 (d, JPC = 1.3 Hz, m-C), 127.9 (d, JPC = 1.7 Hz, p-C), 127.69 (s, m-C), 127.68 (s, p-C), 124.6 (s, i-C), 29.4 (s, C(CH₃)₂), 24.8 (s, CH₃), 22.8 (s, CH₃). IR: v = 2064, 1978, 1909 cm⁻¹ (iCO). Analytical data were found to show a strong dependence on the combustion conditions which implied that even at elevated temperatures no complete combustion could be achieved. As several attempts to establish optimum conditions failed, no meaningful elemental analysis was obtained. The homogeneity of the product was established using spectral data (see ESI†).

5: A solution of Na₂[Fe(CO)₄] (390 mg, 1.12 mmol) in THF (20 ml) was cooled in a dry ice/acetone bath to −78 °C.
A solution of 1 (500 mg, 1.12 mmol) in THF (5 ml) was added dropwise with stirring. The solution was allowed to warm to r.t., stirred for 2 h, and filtered. The solution was again cooled to −78 °C, and another equivalent of 1 (500 mg, 1.12 mmol) was added. Stirring was continued for 2 h during which the mixture was allowed to warm to r.t. Solids were then filtered off, and the solvent was removed under reduced pressure. The remaining dark solid was treated with hexane, the mixture filtered, and the filtrate evaporated to dryness. The residue was dissolved in a minimum amount of hexane and stored at 4 °C, to give 570 mg (55%) of red crystals, m.p. >350 °C (dec.).

(b) Alternatively, 5 was directly accessible from reaction of Collman’s reagent with 2 equiv. of 1: Na₂[Fe(CO)₄] (390 mg, 1.12 mmol) and THF (20 ml) were introduced into a Schlenk flask and stirred for 10 min at r.t. The flask was then cooled to −78 °C in a dry ice-acetone bath, and a solution of 1 (1.00 g, 2.25 mmol) in THF (10 ml) was added dropwise. The mixture was allowed to warm to r.t. and stirred for another 2 h. The solvent was removed under reduced pressure and the remaining dark solid was treated with hexane. The mixture was filtered and the filtrate evaporated to dryness. The residue was dissolved in a minimum amount of hexane and stored at 4 °C, to give 747 mg (72%) of red crystals, m.p. >350 °C (dec.).

Monitoring the further progress of the reaction during slow warming to r.t. allowed us to establish that 8 decays to yield a mixture of 6 and 7. No further intermediates were spectroscopically observable during this process.

6: ⁴¹P[¹H] NMR (CD₂Cl₂): δ = 169.4 (s). ¹H NMR (CD₂Cl₂): δ = 7.07 (m, 6 H, C₆H₃), 5.76 (d, 2 H, jₚH = 11.0 Hz, =CH), 3.75 (sept, 2 H, jₗH = 6.9 Hz, CH(CH₂)₂), 3.41 (sept, 2 H, jₗH = 7.0 Hz, CH(CH₂)₂), 1.96 (d, 3 H, jₚH = 5.2 Hz, PCH₃), 1.48 (d, 6 H, jₗH = 6.8 Hz, CH(CH₂)₂), 1.25 (d, 6 H, jₗH = 6.8 Hz, CH(CH₂)₂), 1.16 (d, 6 H, jₗH = 6.7 Hz, CH(CH₂)₂), 1.08 (d, 6 H, jₗH = 6.7 Hz, CH(CH₂)₂). ¹³C[¹H] NMR (CD₂Cl₂): δ = 212.1 (d, jₚC = 16.9 Hz, CO), 148.5 (d, jₚC = 1.9 Hz, O-C), 134.2 (d, jₚC = 4.6 Hz, i-C), 128.0 (d, jₚC = 1.1 Hz, p-C), 123.0 (s, m-C), 119.9 (d, jₚC = 2.7 Hz, =CH), 29.5 (s, PCH₃), 28.2 (s, C(CH₂)₂), 26.7 (s, C(CH₂)₂), 24.7 (s, CH₃), 21.6 (s, CH₃), 21.1 (s, CH₃). IR: δ = 2039, 1617 cm⁻¹ (CO).

Independent synthesis of 6 and 7. A solution of 1 (1.00 g, 2.25 mmol) in Et₂O was added dropwise to a solution of MeMgI (374 mg, 2.25 mmol) in Et₂O. The mixture was stirred for 18 h. The solvent was then removed under reduced pressure, the solid residue taken up in hexane, and the resulting mixture was filtered. The filtrate was evaporated to dryness under reduced pressure to yield crude 7 (340 mg, 0.73 mmol) which was identified using multinuclear (¹H, ¹³C, ³¹P) NMR data. The phosphine was then dissolved in toluene, solid Fe₂CO₃ (260 mg, 0.73 mmol) was added at r.t., and the resulting mixture was stirred overnight. Volatiles were removed under reduced pressure and the remaining solid was taken up in hexane. Filtration and evaporation of the filtrate to dryness gave 375 mg (87%) of brown-red crystals of 6, m.p. >350 °C (dec.).

7: ³¹P[¹H] NMR (CD₃Cl): δ = 111.9 (s). ¹H NMR (CD₃Cl): δ = 7.2–7.1 (m, 6 H, C₆H₃), 5.74 (d, 2 H, jₚH = 2.0 Hz, =CH), 3.83 (d, 2 H, jₗH = 6.8 Hz, CH(CH₂)₂), 3.83 (d, 2 H, jₗH = 3.8 Hz, CH(CH₂)₂), 1.35 (d, 6 H, jₗH = 6.8 Hz, CH(CH₂)₂), 1.28 (d, 6 H, jₗH = 6.8 Hz, CH(CH₂)₂).

**Reaction of Na₂[Fe(CO)₄] with MeI.** (a) A solution of Na₂[Fe(CO)₄] (390 mg, 1.12 mmol) and THF (5 ml) was added dropwise with stirring. The solution was cooled to −78 °C, and a solution of Na₂[Fe(CO)₄] (500 mg, 1.12 mmol) in THF (5 ml) was added. Stirring was continued for 2 h during which the mixture was allowed to warm to r.t. The mixture was filtered and the filtrate evaporated to dryness. The residue was dissolved in a minimum amount of hexane and stored at 4 °C, to give 570 mg (55%) of red crystals, m.p. >350 °C (dec.).
Crystal structure determinations

Diffraction studies were carried out using a Bruker diffractometer equipped with a Kappa APEX II Duo CCD-detector and a KRYO-FLEX cooling device with Mo-Kα radiation (λ = 0.71073 Å) complexes [PPh₄][2], 3a, 5) or Cu-Kα radiation (λ = 1.54178 Å) complexes 4, 6) at T = 100 K. The structures were solved by direct methods (SHELXS-97) and refined with a full-matrix least-squares scheme on F² (SHELXL-2014 and SHELXL-97). Semi-empirical absorption corrections were applied for all structures. Non-hydrogen atoms were refined anisotropically, and H atoms with a riding model, on isotropic displacement parameters. Details of the crystal structure determinations are listed in Table 1.

[PPh₄][2] is a racemic twin (x = 0.473(15)), and an extinction correction was applied. Furthermore, one solvent molecule (THF) is disordered, and the high Uₜ values in another one indicate a slight disorder, which was not resolved. 4 shows high Uₜ-values for the Fe(CO)₃ moiety as well as for one 2,6-diisopropylphenyl substituent indicating a disorder. The disorder was resolved and modelled for the Fe(CO)₃ moiety, the 2,6-diisopropylphenyl substituent and one iPr-group of the other 2,6-diisopropylphenyl substituent. Disordered C- and O-atoms in [PPh₄][2] and 4 were refined isotropically, and the Fe-atoms were refined anisotropically (see the cif-files for further details).

Computational studies

Computational studies were performed with the Gaussian03 suite of programs using def2-tzvp basis sets (obtained from the basis set exchange home page) on model compounds 2', [Li(OMe₂)₃][2'], 3' and 5' featuring NMe instead of the larger NDipp substituents. Solvent effects were included by using a PCM model as implemented in the Gaussian package (SCRF = THF). Molecular structures were first energy optimized without symmetry constraints. Calculation of harmonic vibrational frequencies was performed in order to ensure that all stationary points located were of local minima on the energy hypersurface (in case of [2'[Li(OMe₂)₃]], the molecular structure had to be re-optimized using a smaller def2-svp basis set for the [Li(OMe₂)₃]⁺ cation, and the frequency calculation was performed at the same level. The structural features of both models showed no significant deviations). The NBO analysis was performed with the NBO 3.1 program as implemented in the Gaussian package. MOLDEN was used for the visualization of Kohn–Sham orbitals.
