VI. The dynamical structure of PLCKG214.6+37.0, a Planck discovered triple system of galaxy clusters

(Affiliations can be found after the references)

Received 17 July 2012 / Accepted 22 October 2012

ABSTRACT

The survey of galaxy clusters performed by Planck through the Sunyaev-Zeldovich effect has already discovered many interesting objects, thanks to its full sky coverage. One of the SZ candidates detected in the early months of the mission near to the signal-to-noise threshold, PLCKG214.6+37.0, was later revealed by XMM-Newton to be a triple system of galaxy clusters. We present the results from a deep XMM-Newton re-observation of PLCKG214.6+37.0, part of a multi-wavelength programme to investigate Planck discovered superclusters. The characterisation of the physical properties of the three components has allowed us to build a template model to extract the total SZ signal of this system with Planck data. We have partly reconciled the discrepancy between the expected SZ signal derived from X-rays and the observed one, which are now consistent within 1.2σ. We measured the redshift of the three components with the iron lines in the X-ray spectrum, and confirm that the three clumps are likely part of the same supercluster structure. The analysis of the dynamical state of the three components, as well as the absence of detectable excess X-ray emission, suggests that we are witnessing the formation of a massive cluster at an early phase of interaction.

Key words. galaxies: clusters: general – large-scale structure of Universe – galaxies: clusters: individual: PLCKG214.6+37.0

Article published by EDP Sciences A132, page 1 of 14
1. Introduction

Clusters of galaxies occupy a special position in the hierarchy of cosmic structures, because they are the largest objects that decoupled from the cosmic expansion and that have had time to undergo gravitational collapse. They are thought to form via a hierarchical sequence of mergers and accretion of smaller systems driven by gravity. During this process the intergalactic gas is heated to high X-ray emitting temperatures by adiabatic compression and shocks and settles in hydrostatic equilibrium within the cluster potential well. Sometimes galaxy clusters are found in multiple systems, super-cluster structures that already decoupled from the Hubble flow and are destined to collapse. The crowded environment of superclusters is an ideal place to study the merging processes of individual components at an early stage of merging and to witness the initial formation phase of very massive structures. Moreover, the processes related to the contraction may increase the density of the intercluster medium and make it observable with current instruments. An example is the central complex of the Shapley concentration, which has been the object of extensive multi-wavelength observations with the aim of characterising the merger processes in galaxy clusters (e.g. Kull & Böhringer 1999; Bardelli et al. 1998; Rossetti et al. 2007; Giacintucci et al. 2005).

Recently a new observational window has opened up for the study of the astrophysics of galaxy clusters through the Sunyaev-Zeldovich effect (Sunyaev & Zeldovich 1972, SZ hereafter): a spectral distortion of the cosmic microwave background (CMB) generated through inverse Compton scattering of CMB photons by thermal electrons in the intracluster medium (ICM). SZ surveys are discovering new clusters, some of which are interesting merging systems (with “El Gordo”, Menanteau et al. 2012, being the most prominent example).

A key role in SZ science is now played by the Planck satellite. Compared to other SZ surveys of galaxy clusters, Planck has only moderate band-dependent spatial resolution, but it possesses a unique nine-band coverage, and more crucially it covers the whole sky. Therefore, it allows the rarest objects to be detected: massive high-redshift systems (Planck Collaboration 2011f), which are the most sensitive to cosmology; and complex multiple systems, which are interesting for the physics of structure formation. Indeed, during the follow-up XMM-Newton campaign of Planck SZ candidates, we found two new double systems and two new triple systems of clusters (Planck Collaboration 2011c, hereafter Paper I). In all cases, the cumulative contribution predicted by X-ray measurements was lower than the measured SZ signal, although compatible within 3σ.

PLCKG214.6+37.0 is the most massive and the X-ray brightest of the two Planck discovered triple systems. The XMM-Newton follow-up observations showed that the Planck SZ source candidate position is located ~5′ from the two southern components (A and B). A third clump, C, lies approximately 7′ to the north (Fig. 1). The X-ray spectral analysis of component A indicated a redshift of z_A = 0.45, consistent with two galaxies with spectroscopic redshift of ~0.45, close to the peaks of components A and C. A cross-correlation with SDSS-DR7 luminous red galaxies and the supercluster catalogue from the SDSS-DR7 (Liivamägi et al. 2012) hinted that this triple system is encompassed within a very large-scale structure located at z ~ 0.45, and whose centroid lies about 2 deg to the south (see Appendix B in Paper I for further details).

In this paper we present new SZ measurements of this object with Planck and compare them with the results from a a deep XMM-Newton re-observation. In Sect. 2 we describe the analysis methods and the Planck and XMM-Newton data used in this paper. In Sect. 3 we present our results obtained with X-ray and, in Sect. 4, compare them with available optical data from SDSS. In Sect. 5 we compare the X-ray results with Planck results. In Sect. 6 we discuss our findings.

Throughout the paper we adopt a ΛCDM cosmology with H_0 = 70 km s^{-1} Mpc^{-1}, Ω_M = 0.3, and Ω_Λ = 0.7. At the nominal redshift of the supercluster, z = 0.45, one arcminute corresponds to 350 kpc.

2. Observations

2.1. Planck data and analysis

Planck (Tauber et al. 2010; Planck Collaboration 2011a) is the third-generation space mission to measure the anisotropy of the CMB. It observes the sky in nine frequency bands covering 30–857 GHz with high sensitivity and angular resolution from 3′ to 5′. The Low Frequency Instrument (LFI; Mandolesi et al. 2010; Bersanelli et al. 2010; Mennella et al. 2011) covers the 30, 44, and 70 GHz bands with amplifiers cooled to 20 K. The High Frequency Instrument (HFI; Lamarre et al. 2010; Planck HFI Core Team 2011a) covers the 100, 143, 217, 353, 545, and 857 GHz bands with bolometers cooled to 0.1 K. Polarisation is measured in all but the two highest bands (Leahy et al. 2010; Rosset et al. 2010). A combination of radiative cooling and three mechanical coolers produces the temperatures needed for the detectors and optics (Planck Collaboration 2011b). Two data processing centres (DPCs) check and calibrate the data and make maps of the sky (Planck HFI Core Team 2011b; Zacchei et al. 2011). Planck’s sensitivity, angular resolution, and frequency coverage make it a powerful instrument for Galactic and extragalactic astrophysics, as well as for cosmology. Early astrophysics results are given in Planck Collaboration (2011b–z).

Our results are based on the SZ signal as extracted from the six bands of HFI corresponding to the nominal Planck survey of 14 months, during which the whole sky was observed twice. We refer to Planck HFI Core Team (2011b) and Zacchei et al. (2011) for the generic scheme of TOI processing and map making, as well as for the technical characteristics of the maps used. We adopted a circular Gaussian as the beam pattern for each frequency, as described in Planck HFI Core Team (2011b); Zacchei et al. (2011).

The total SZ signal is characterised by the integrated Compton parameter Y_{500} defined as \( D_A(z) Y_{500} \) \( = (\sigma_T m_e c^2) \int P_{\theta} dV \), where \( D_A(z) \) is the angular distance to a system at redshift z, \( \sigma_T \) is the Thomson cross-section, c the speed of light, m_e the rest mass of the electron, P_{\theta} the pressure of thermal electrons, and the integral is performed over a sphere of radius R_{500}.

The extraction of the total SZ signal for this structure is more complicated than for single clusters. Owing to its moderate spatial resolution, Planck is not able to separate the contributions of the three components from the whole signal. In Paper I, we estimated the total flux assuming a single component with mass corresponding to the sum of the masses of the three clumps, 1

\footnote{Planck (http://www.esa.int/Planck) is a project of the European Space Agency (ESA) with instruments provided by two scientific consortia funded by ESA member states (in particular the lead countries: France and Italy) with contributions from NASA (USA), and telescope reflectors provided in a collaboration between ESA and a scientific consortium led and funded by Denmark.}
Fig. 1. Triple systems PLCKG214.6+37.0. Left upper panel: Planck SZ reconstructed map (derived from the Modified Internal Linear Combination Analysis, Hurier et al. 2010), oversampled and smoothed for display purposes. Right upper panel: XMM-Newton wavelet filtered image in the [0.5–2.5] keV range (Sect. 2.2). The three components of PLCKG214.6+37.0 are marked with circles (with radius $R_{500}$, see Table 1) and indicated with letters as in the text. The X-ray structure visible in the north-east (marked with an asterisk) is likely associated with the active galaxy SDSSJ090912.15 + 144613.7, with a spectroscopic redshift $z = 0.767$. Left lower panel: Raw MOS count rate (counts s$^{-1}$) image in the [0.5–2.5] keV range, corrected for vignetting. The black circles mark the point sources detected by our algorithm, which we masked during the analysis (Sect. 2.2). The pixel size in this image is 4.35′. Right lower panel: SDSS r-band image of the PLCKG214.6+37.0 field. In all panels, north is up and east to the left, and we overlay X-ray contours, computed on the wavelet-filtered image logarithmically spaced starting from the level where a connection is seen between all components (Sect. 3.4).

following a universal pressure profile (Arnaud et al. 2010) centred at the barycentre of the three components. This is obviously only a simple first-order approach. The wealth of information that is now available on this system has allowed us to build a more representative model. With the X-ray constraints on the structural properties of clumps A, B, and C (Sect. 3.1), we are now able to build a three-component model. As discussed in Planck Collaboration (2011d), our baseline pressure profile is the standard “universal” pressure profile derived by Arnaud et al. (2010). We assumed this profile for each clump, parametrised in size by the respective X-ray scale radius, $R_{500}$. The normalisations, expressed as integrated Comptonisation parameters within 5 $R_{500}$ were tied together according to the ratio of their respective $Y_{X,500}$ values, as determined from the X-ray analysis. Thus only one overall normalisation parameter remains to be determined. Such a template used under these assumptions and parametrisations, together with the multi-frequency matched filter algorithm, MMF3 (Melin et al. 2006), directly provides the integrated SZ flux over the whole structure.
The two-dimensional reconstruction of the Comptonisation parameter, \( y = (\sigma T / m_e c^2) \int P_{\rm ad} \, dl \), provides a way to map the spatial distribution of the thermal pressure integrated along the line of sight. This is performed using the modified internal linear combination method (MILCA, Hurier et al. 2010) on the six Planck all-sky maps from 100 GHz to 857 GHz. MILCA is a component separation approach aimed at extracting a chosen component (here the thermal SZ signal) from a multi-channel set of input maps. It is primarily based on the ILC approach (e.g., Eriksen et al. 2004), which searches for the linear combination of the input maps that minimises the variance of the final reconstructed map imposing spectral constraints.

2.2. XMM-Newton observation and data reduction

PLCKG214.6+37.0 was observed again by XMM-Newton during AO10, for a nominal exposure time of 65 ks. We produced calibrated event files from observation data files (ODF) using v.11.0 of the XMM-Newton Science Analysis Software (SAS). We cleaned the event files from soft proton flares, using a double filtering process (see Bourdin & Mazzotta 2008 for details). After the cleaning, the net exposure time is \( \sim 47 \) ks for the MOS detectors and \( \sim 37 \) ks for the pn camera. Since a quiescent component of soft protons may survive the procedure described above, we calculated the “in over out ratio” \( R_{\text{SB}} \) (De Luca & Molendi 2004) and found values close to unity, suggesting a negligible contribution of this component. We masked bright point sources, detected in the MOS images as described in Bourdin & Mazzotta (2008). We performed the same data reduction procedure on the snapshot observation 0656200101, finding a cleaned exposure time of \( \sim 15 \) ks for the MOS and \( \sim 10 \) for the pn.

We then combined the two observations and binned the photon events in sky coordinates and energy cubes, matching the angular and spectral resolution of each focal instrument. For spectroscopic and imaging purposes, we associated an “effective exposure” and a “background noise” cube to this photon cube (see Bourdin et al. 2011 for details). The “effective exposure” is computed as a linear combination of CCD exposure times related to individual observations, with local corrections for useful CCD areas, RGS transmissions, and mirror vignetting factors. The “background noise” includes a set of particle background spectra modelled from observations performed with the closed filter. Following an approach proposed in e.g., Leccardi & Molendi (2008) or Kuntz & Snowden (2008), this model sums a quiescent continuum to a set of fluorescence emission lines convolved with the energy response of each detector. Secondary background noise components include the cosmic X-ray background and Galactic foregrounds. The cosmic X-ray background is modelled with an absorbed power law of index \( \Gamma = 1.42 \) (e.g., Lumb et al. 2002), while the Galactic foregrounds are modelled by the sum of two absorbed thermal components accounting for the Galactic transabsorption emission \( (kT_1 = 0.099 \, \text{keV and } kT_2 = 0.248 \, \text{keV, Kuntz & Snowden 2000}) \). We estimate emissivities of each of these components from a joint fit of all background noise components in a region of the field of view located beyond the supercluster boundary.

To estimate average ICM temperatures, \( kT \) along the line of sight and for a given region of the field of view, we added a source emission spectrum to the “background noise”, and fitted the spectral shape of the resulting function to the photon energy distribution registered in the 0.3–10 keV energy band. In this modelling, the source emission spectrum assumes a redshifted and nH absorbed emission modelled from the Astrophysical Plasma Emission Code (APEC, Smith et al. 2001), with the element abundances of Grevesse & Sauval (1998) and neutral hydrogen absorption cross-sections of Balucinska-Church & McCammon (1992). It is corrected for effective exposure, altered by the mirror effective areas, filter transmissions and detector quantum efficiency, and convolved by a local energy response matrix.

The X-ray image shown in Fig. 1 (upper left) is a wavelet-filtered image, computed in the 0.5–2.5 keV energy band. To generate this image, we corrected the photon map for effective exposure and soft-thresholded its undecimated B3-spline wavelet coefficients (Starck et al. 2007) to a 3 \( \sigma \) level. In this procedure, significance thresholds have been directly computed from the raw (Poisson distributed) photon map, following the multi-scale variance stabilisation scheme introduced in Zhang et al. (2008). We applied the same transformation to a “background noise” map, which we then subtracted from the image. The wavelet filtering allows us to reduce the amplitude of the noise that dominates the raw images (see Fig. 1, lower left) and to map the distribution of the ICM on different scales (see the pioneering works by Slezak et al. 1994; Vikhlinin et al. 1997; Starck & Pierre 1998).

3. Structure of the clusters from X-rays

3.1. Global analysis of the cluster components

Assuming that the three structures are located at the same redshift, \( z = 0.45 \) (the spectroscopic value found in Paper I), from the combination of the two XMM-Newton observations we have carried out an X-ray analysis for each component independently (we masked the two other clumps while analysing the third one). We extracted surface brightness profiles of each component, centred on the X-ray peak, in the energy band 0.5–2.5 keV. We used the surface brightness profile to model the three-dimensional density profile: the parametric density distribution (Vikhlinin et al. 2006) was projected, convolved with the PSF and fitted to the observed surface brightness profile (Boardin et al. 2011). From the density profile we measured the gas mass, \( M_{500} \), which we combined with the global temperature \( T_X \), obtained with the spectral analysis, to measure \( Y_X = M_{500} * T_X \) (Kravtsov et al. 2006). We used the \( M_{500} - Y_X \) scaling relation in Arnaud et al. (2010) to estimate the total mass \( M_{500} \), defined as the mass corresponding to a density contrast \( \delta = 500 \) with respect to the critical density at the redshift of the cluster, \( \rho_c(z) \), thus \( M_{500} = (4\pi/3)500\rho_c(z)R_{500}^3 \). The global cluster parameters were estimated iteratively within \( R_{500} \), until convergence.

The resulting global X-ray properties are summarised in Table 1. The \( Y_X \) and \( M_{500} \) values are slightly higher, but consistent within 1.5 \( \sigma \), with the results presented in Paper I.

3.2. Redshift estimates

Crucial information on the nature of this triple system comes from measuring the redshift of each component, allowing us to assess whether this is a bound supercluster structure or a combination of unrelated objects along the same line of sight. In Paper I, a reliable redshift measurement, obtained with the short XMM-Newton observation, was only available for component A. Its value \( z = 0.45 \) was consistent with the only two spectroscopic redshifts available in this field and corresponding to the bright central galaxies in components A (SDSSJ090849.38 + 143830.1 \( z = 0.450 \)) and C (SDSSJ090851.2 + 144551.0 \( z = 0.452 \)). A photometric redshift, \( z = 0.46 \), was furthermore
available for a bright galaxy (SDSSJ090902.66 + 143948.1) very close to the peak of component B.

With the new XMM-Newton observation, we detect the iron K complex in each clump. We extracted spectra in a circle centred on each component with radius $R_{500}$ (Table 1). We performed a more standard spectral extraction and analysis than the one described in Sect. 2.2, extracting in each region the spectrum and the source-to-background ratio, a redshift measurement (see Planck Collaboration 2011c for details). We first performed a more standard spectral extraction and analysis than the joint MOS2 and pn spectra. We performed simulations within XSPEC, modelling the instrumental and cosmic background as in Leccardi & Molendi (2008), leaving as free parameters of the fit the temperature, metal abundance, redshift, and normalisation of the cluster component (see Planck Collaboration 2011c for details). We first fitted spectra for each detector separately. While the MOS detectors do not show any instrumental line in the whole 4–5 keV range (Leccardi & Molendi 2008), the pn detector shows a faint fluorescent line in the spectral range where we expect to find the redshifted cluster line. We verified that this feature does not significantly affect our results, since the pn redshift and metal abundance are always consistent with at least one of the MOS detectors. We report our results in Table 2.

For components A and C the redshift measurements for each detector are consistent within 1σ and we performed joint fits combining all instruments (Table 2). For component B, the redshift measurement with MOS1 is higher than the estimates with the other detectors, although consistent within 2σ. The joint fit of the three detectors in this case would lead to a best fit value $z = 0.516 (−0.023, +0.014)$, while combining only MOS2 and pn we find $0.491 (−0.011, +0.013)$. In the joint fit of the three detectors, the MOS1 spectrum drives the redshift estimate, leaving many residuals around the position of the iron lines for the MOS2 and pn spectra. We performed simulations within XSPEC to quantify the probability that, given the statistical quality of the spectra and the source-to-background ratio, a redshift measurement as high as $z = 0.529$, may result just from statistical fluctuations of a spectrum with $z = 0.48$. We assumed the best fit model of the joint MOS2 and pn analysis as the input source and background model with a redshift $z = 0.48$ and we generated 1500 mock spectra that we fitted separately with the same procedure we used for the real spectrum. We found a higher redshift than what we measured with MOS1 in 3% of the simulated spectra. With these simulations, we also reproduced the joint fit procedure: we performed 500 joint fits of three simulated spectra and found that a redshift as high as 0.516 occurs with less than 1% probability. Furthermore, we performed other simulations assuming the redshift resulting from the joint fit of the three detectors, $z = 0.516$: the probability of finding two redshifts as low as $z = 0.475$ is about 1.7%. The simulations we have described show that it is unlikely that the three redshift measurements and the joint fit we obtained for subcluster B may result from statistical fluctuations of the same input spectrum, suggesting a systematic origin for the discrepancy between MOS1 and the other detectors. Indeed, the quality of the fit with the MOS1 data alone is worse than with the other detectors, exhibiting strong residuals around the best fit model. We verified the possibility of a calibration issue affecting MOS1 by checking the position of the instrumental lines: we did not find any significant systematic offset for the bright low-energy AI and SI lines, but the absence of strong fluorescent lines between 2 and 5.4 keV did not allow us to test the calibration in the energy range we are interested in. Although the origin of the systematic difference of the MOS1 spectrum is still unclear, we decided to exclude this detector when estimating the redshift of component B (Table 2). Nonetheless, in the following, we also discuss the possibility that the cluster is located at the higher redshift $z = 0.516$. Concerning the components A and C, the redshift measurements are not significantly affected if we exclude the MOS1 detector.

The redshift estimates we obtained from X-ray data for components A ($z = 0.445 (±0.006)$ and C ($z = 0.46 ± 0.01$) are nicely consistent with the spectroscopic values found in the SDSS archive for their central brightest galaxies (0.450 and 0.452, respectively). Concerning component B, even without considering the MOS1 detector, we still find a higher best fit value ($z = 0.48 ± 0.01$) with respect to the other two components. This is shown in Fig. 2, where we compare the variation of $\chi^2$ for the joint fits (see Table 2) of the three components. While component A and C are consistent with being at the same redshift at less than 1σ, component B is likely located at a higher redshift, although consistent at less than 2σ with the position of the other clusters. Therefore, component B is likely separated along the line of sight from the two other components by 69 (±30, +25) Mpc (150 Mpc, if we consider the redshift estimate obtained with the three detectors). While this large separation suggests that the cluster B is not interacting with the other components, it is still consistent with the three objects being part of the same supercluster structure (Bahcall 1999).

Using the best fit redshift estimates for the three components, we recomputed the physical parameters in Table 1. While the variations for cluster A and C are negligible, for cluster B we found $Y_X = (0.74 ± 0.19) \times 10^{14} M_{⊙}$ keV, $M_{500} = (1.89 ± 0.20) \times 10^{14} M_{⊙}$ and $R_{500} = (726 ± 25)$ kpc.

3.3. Radial structural analysis of the components

We performed a radial analysis of the X-ray observations of PLCKG214.6+37.0 to study the behaviour of the main thermodynamical quantities of the ICM. We extracted the X-ray brightness profile as discussed in Sect. 3.1: while the A component shows a very peaked profile, which might indicate a cool core state, the B and C components have flatter profiles at the centre, a signature of an un-relaxed dynamical state. On a more quantitative basis, we extracted the three-dimensional density profiles for each component, with the parametric procedure discussed in Sect.3.1, and computed the scaled central density, $n_0 E(z)^{-2}$, where $E(z) = \Omega_m (1+z)^{3} + \Omega_{\Lambda}$ is the ratio of the Hubble constant at redshift $z$ with respect to its present value $H_0$. This parameter can be used to classify clusters into cool-core (n_0 E(z)^{-2} > 4 \times 10^{-2} \text{cm}^{-3}) and non cool-core objects (Pratt et al. 2009). As expected, A shows a central density (n_0 E(z)^{-2} = 7 \times 10^{-2} \text{cm}^{-3}) typical of cool-core objects, while B and C show much lower central densities (n_0 E(z)^{-2} = 2 \times 10^{-3} \text{cm}^{-3}, both).

We extracted spectra in four (three for component C) annuli and fitted them with a single-temperature absorbed model, fixing as many components as we could because of the faintness of the source; $nH$ was fixed to the Galactic value (Dickey & Lockman 1990), redshift of the three components to 0.45; and we also fixed all parameters of the background components. In most cases we also fixed the metallicity to 0.3 $Z_{\odot}$, except in the centre of subcluster A, where we could estimate an excess of metal abundance ($Z = 0.6 \pm 0.1 Z_{\odot}$), as often found in cool cores. All temperature profiles are consistent at 1σ with being flat and with the global values shown in Table 1, therefore from now on we will consider them to be isothermal.

We combined the three-dimensional density profile and the global temperature to derive two other thermodynamic quantities: pressure and entropy\(^3\). Pressure is especially relevant to our analysis since it is the quantity that is measured directly through the SZ effect. We have fitted the profiles with the model described in Arnaud et al. (2010), and the best fit parameters are consistent with the ones for relaxed cool core objects for component A, and for disturbed objects for components B and C.

Entropy is a thermodynamic quantity that is connected both to the accretion history of the cluster and to non gravitational processes. If we fit the profile with a power law plus a constant, the central entropy $K_0$ is a good indicator of the cool core state (Cavagnolo et al. 2009). The central entropy values are essentially driven by the central densities because we assumed a constant temperature, given the large uncertainties and poor resolution of the temperature profiles. As expected, for subcluster A we found $K_0 = (13 \pm 2) \text{keV cm}^2$, a central entropy typical of cool core systems, while for B and C we found higher values ($K_0 = 142 \pm 10 \text{keV cm}^2$ and $K_0 = 153 \pm 18 \text{keV cm}^2$, respectively) typical of unrelaxed objects.

3.4. 2D structure of the components and of the supercluster

A qualitative analysis of the X-ray image (Fig. 4) shows that the two southern components are apparently connected. Indeed the X-ray surface brightness isophotes of component B (Fig. 1) are slightly elongated in the direction of component A, as often observed in pairs of merging clusters (e.g., the three systems in Maurogordato et al. 2011; and the pair A399-A401 in Sakelliou & Ponman 2004). We visually investigated the possible connection between the components by drawing constant surface brightness contours in the X-ray image. The appearance of the contours may provide information about the two-dimensional distribution of the intracluster gas and the possible contamination by residual point sources. A connection between the components A and B is robustly detected, at a contour level above the background intensity (inner contour in Fig. 4). However, with this simple analysis it is not possible to assess whether this connection is physical or only a projection effect. We used the same method between A and C where we start to see a connection at a much lower intensity, about 25% of the level of the background model in the same region (outer contour in Fig. 4). In this regime, it might still be possible that the connection between the two components is due to uncertainties in background estimation or to residual point sources.

On a more quantitative basis, we extracted longitudinal surface brightness profiles in the east-west direction across components A and B, and in the north-south direction, across components A and C (in the boxes shown in Fig. 4). The profile across components A and B (Fig. 5, left panel) shows clearly enhanced emission with respect to the opposite direction between the two clumps: we modelled the emission of each component by taking the data in the external part of the pair and projecting it symmetrically in the direction of the possible interaction. In the region where the two emissions overlap, we summed the two models and found their sum to be consistent with the data. The two objects are very close in the plane of the sky and their emissions apparently overlap at less than $R_{500}$ (Fig. 1); if they were located at the same distance from us and interacting we would expect to see compression and enhanced X-ray emission between the two objects. This is not the case here, so our results argue in favour of a separation along the line of sight of the two components, possibly still in an early phase of interaction.

Concerning components A and C, their separation in the plane of the sky is $7.4'$, corresponding to $\approx 2.5$ Mpc at $z = 0.45$. The analysis of the longitudinal surface brightness profile across them (Fig. 5, right panel) confirms our earlier indication: the emission in the intersection region is not significantly detected and is consistent with the “undisturbed” model (derived as before).

\(^3\) The “X-ray astronomer’s entropy” is defined as $K = kT/n_e^{3/2}$, where $n_e$ is the electron density and $T$ the X-ray temperature. This quantity is related to the thermodynamic entropy by a logarithm and an additive constant.
These results suggest that the three clusters, while likely belonging to the same structure, have not started to fully interact yet.

4. Comparison with optical data

Since the sky region of PLCKG214.6+37.0 is covered by the Sloan Digital Sky Survey (SDSS), we retrieved a galaxy catalogue from SDSS Data Release 8 (DR8). It covers a circular area of 20′ radius around the barycentre of PLCKG214.6+37.0 and includes optical magnitudes and photometric redshifts (see Abazajian et al. 2009, for a description of measurements and calibration of photometric redshifts in SDSS DR8). It contains about 2000 objects, around 900 of which are in the redshift range 0.35–0.6. Unfortunately, spectroscopic redshifts are available only for the brightest central galaxies of components A and C, thus we relied on photometric redshifts alone in our analysis. Spectroscopic information on this system will be available.
from our follow-up programme and will be discussed in a forthcoming paper.

4.1. Photometric redshifts of the three components

We used the archival photometric redshifts in our catalogue to estimate the redshift of the three components. We extracted a sub-catalogue selecting only galaxies in the photometric redshift range 0.35–0.6 and, for each clump, we calculated the median redshift of the galaxy population around the X-ray centre as a function of the cutoff radius. The resulting plot is shown in Fig. 6. Components A and C are both consistent with the spectroscopic value of their central galaxies (z = 0.45), but the innermost 2\s9 of component B indicate a slightly higher redshift (\zphot \approx 0.47), similar to the results of the X-ray analysis, although consistent at 2\s9 with the values of the other components. At larger radii, the redshift estimates for the three clumps are all consistent with each other. It should be noted however that components A and B are separated only by \approx 2\arcmin, thus all the estimates at similar or larger radii may be contaminated by galaxies belonging to the other cluster.

4.2. Optical appearance and morphology of the cluster

We used the catalogue from SDSS to build two-dimensional galaxy density maps in different photometric redshift cuts (Fig. 7), with a width \Delta\zphot = 0.04. We assigned the galaxies to a fine grid of 24\arcmin per pixel, which is then degraded with a Gaussian beam to an effective resolution of 3\arcmin. We also computed a significance map using as reference ten random non-overlapping control regions in a 9 deg\arcmin area around the system.

Clear galaxy overdensities show up around \zphot = 0.46 at the location of the three X-ray clumps. However, these overdensities do not appear isolated. At the location of cluster B, we see an overpopulation of galaxies towards higher redshift (5\s9 peak at \zphot \approx 0.5), consistent with the redshift z = 0.48 we found in X-rays, whereas the overdensity extends towards slightly lower redshifts (\zphot \approx 0.42) at the position of cluster A. There are also indications of another concentration close to component B at higher redshift (0.52–0.6).

We investigated the maps in Fig. 7 to look for a possible connection between the components. The green and yellow regions show where we extracted longitudinal profiles.

We used the archival photometric redshifts in our catalogue to estimate the redshift of the three components. We extracted a sub-catalogue selecting only galaxies in the photometric redshift range 0.35–0.6 and, for each clump, we calculated the median redshift of the galaxy population around the X-ray centre as a function of the cutoff radius. The resulting plot is shown in Fig. 6. Components A and C are both consistent with the spectroscopic value of their central galaxies (z = 0.45), but the innermost 2\s9 of component B indicate a slightly higher redshift (\zphot \approx 0.47), similar to the results of the X-ray analysis, although consistent at 2\s9 with the values of the other components. At larger radii, the redshift estimates for the three clumps are all consistent with each other. It should be noted however that components A and B are separated only by \approx 2\arcmin, thus all the estimates at similar or larger radii may be contaminated by galaxies belonging to the other cluster.

5. Comparison with Planck

5.1. Total SZ signal

As a simple comparison of the SZ and X-ray properties, we can compare the Planck Y measurement with the predicted values from the sum of the YX estimates of all three components, using the scaling relations in Arnaud et al. (2010). From our X-ray estimates (Table 1), we predict the total integrated value of the Comptonisation parameter within a sphere of radius 5 R500 for the sum of the three components to be YX,5 R500 = (7.52 \pm 0.9) \times 10^{−4} \arcmin^2. This is about 50% of the measured signal in the same region which was found in Paper I and the two values are compatible within 2.3\s9.

In the following, we work under the assumption that the three clusters are all located at the same redshift z = 0.45. Considering the best fit redshift for component B leads to a slightly smaller SZ flux YX,5 R500 = (6.44 \pm 0.7) \times 10^{−4} \arcmin^2.

As discussed in Sect. 2.1, we used the parameters provided in Table 1 to improve our estimate of the total SZ signal of this structure from Planck data. We built a specific template from the X-ray analysis, made from three universal pressure profiles cut to 5 R500 (Arnaud et al. 2010) corresponding to the three components. Each component is placed at its precise coordinates and the size is given by the R500 value in Table 1. We also fixed the relative intensity between the components to verify A/C = 0.96/1.61 and B/C = 1.22/1.61 for the ratio of integrated fluxes. Then we ran the MMF3 algorithm (Melin et al. 2006) to estimate the amplitude of the template (and hence the total SZ signal of the whole system), and we found Y3 R500 = (12\pm3) \times 10^{−4} \arcmin^2, when centring the map on component B. Our estimate of the supercluster SZ flux is slightly larger than the X-ray prediction but consistent at 1.3\s9 (1.8\s9 using z = 0.516 for component B). We further allowed the position of the template to be a free parameter and found that the algorithm is able to reconstruct the position of the peak with a positional accuracy of one sky pixel (1.7 \times 1.7 \arcmin^2 in a HEALPIX projection of Nside = 2048).
Planck Collaboration: The dynamical structure of PLCKG214.6+37.0, a Planck discovered triple system of galaxy clusters

5.2. SZ signal distribution

It is possible to combine the X-ray images with the temperatures of the components to predict the distribution of the SZ signal (see Mroczkowski et al. 2012, for a similar approach). X-ray images in the soft band are proportional to the square of the density integrated along the line of sight and therefore their square root can be combined with a temperature map to derive a pseudo-pressure map\(^6\), which when smoothed with the \textit{Planck} resolution, can be qualitatively compared with the \(y\)-maps. We combined the background-subtracted X-ray image with a temperature map, built assuming the mean temperature value in each component (Table 1) within \(R_{500}\) and zero outside, to produce a pseudo-pressure map, that we smoothed with a Gaussian filter of 10\('\) FWHM to mimic the resolution of \textit{Planck} \(y\)-maps. \textit{Planck} cannot spatially resolve the three components of this object, therefore we expect the peak of the pseudo-pressure map to be located around the barycentre of the system, just because of resolution effects. The results are shown in Fig. 8, compared with the MILCA \(y\)-map. The position of the peak in the \(SZ\) map does not coincide with the peak of the pseudo pressure map: while the latter is located as expected at the barycentre between the three components, the \(y\)-map suggests an excess of pressure to the SW of component A. The offset between the two peaks is \(\approx 5\)'.

We have performed some tests both on the X-ray and on the \(SZ\) maps to investigate the origin of this offset. On the X-ray side, we have produced surface brightness images using a different background modelling. The first test concerns the background subtraction: we used the ESAS software\(^7\) to produce particle background and residual soft proton images and we created images of the “sky background” components (CXB and Galactic foregrounds), modelling them in an external annulus (Leccardi & Molendi 2008) and rescaling them across the field of view (Ettori et al. 2010). Point sources could also affect the position of the pseudo pressure peak, therefore

\(\int n^2 dl\) and its square root is never equal to \(\int n dl\), which is the expression that should enter in the definition of the Comptonisation parameter \(y\). However, pseudo-pressure maps can still be used for qualitative comparison with the \(y\)-maps.

\(^6\) Although deriving pseudo-pressure maps as discussed in the text is customary in the literature, we underline here that this approach is not completely valid. The X-ray surface brightness, ignoring the temperature dependence, is proportional to \(\int n^2 dl\) and its square root is never equal to \(\int n dl\), which is the expression that should enter in the definition of the Comptonisation parameter \(y\). However, pseudo-pressure maps can still be used for qualitative comparison with the \(y\)-maps.

\(^7\) \url{http://heasarc.nasa.gov/docs/xmm/xmmhp_xmmesas.html}
we ran a different point source algorithm using the SAS task edetect_chain on MOS and pn images in five energy bands, and we added undetected sources we identified with a visual inspection of the images. Both these tests showed a negligible impact on the position of the peak, which in fact is located where it is expected to be, at the barycentre of the three components.

For the SZ effect, we have compared the maps reconstructed with different ILC-based algorithms. Besides MILCA, we tested GMCA (Bobin et al. 2008) and NILC (Delabrouille et al. 2009) algorithms (see Planck Collaboration 2013, for a summary description and a comparison at the cluster scale of the three methods). The three $y$-maps are very consistent and the position of the peak does not change across the maps.

We also compared $y$-maps obtained with different releases of the data finding $\approx 5'$ discrepancies in the position of the peak, comparable to the offset between the X-ray and $y$-maps peaks, discussed above. Indeed the $y$-map presented in Paper I showed a qualitative agreement with X-ray contours. We performed dedicated Monte Carlo simulations to estimate the expected error in the reconstruction of the position of PLCKG214.6+37.0. The presence of correlated noise in the $y$-map produced from Planck data can be a major source of error in reconstructing the position of clusters, in particular in the case of low signal.
to noise systems such as PLCKG214.6+37.0. We first estimated the noise covariance matrix on the Planck Comptonisation parameter map of this system and produced 500 realisations of noise, to each of which we added the expected thermal SZ effect from PLCKG214.6+37.0 to construct mock $y$-maps. Then, we estimated the position of the supercluster in each of these maps. Finally, we computed the average and the standard deviation of the error on the reconstructed position and we obtained an average error of $(4.5\pm 2.5)$ arcmin. Therefore, the offset between the reconstructed positions from the Planck $y$-map and the pseudo-pressure X-ray derived map of PLCKG214.6+37.0 is consistent with being due to noise. The same applies for the separation between the peak in the Planck $y$-map we show here and the one that was shown in Paper I.

6. Discussion and conclusion

The first observations of the multi-wavelength follow-up campaign of PLCKG214.6+37.0, a triple system of galaxy clusters discovered by Planck, have allowed us to improve our understanding of this object. With the new XMM-Newton observation we estimated the global properties of each component: the ICM temperatures range from 3.5 to 5 keV and the total masses within $R_{500}$ are in the range $(2.2\pm 0.3) \times 10^{14} M_\odot$. We detected the iron Kα lines in the X-ray spectra of each component, and therefore we were able to confirm that components $A$ and $C$ are lying at the same redshift ($z = 0.45$). However, given the large angular separation of these two components ($7.5'$, corresponding to 2.6 Mpc, in the plane of the sky), they are likely undergoing a very early stage of interaction and we did not detect significant excess X-ray emission between these two components. For component $B$, we estimated a higher redshift from X-ray spectroscopy ($z = 0.48$), although consistent at 2$\sigma$ with the best fit value for component $A$. A similar indication is supported by the optical data, with the photometric redshifts we retrieved from SDSS DR8. However, given the large uncertainties of our redshift estimates (based both on X-rays and on photometry), a more detailed picture of the three-dimensional structure of PLCKG214.6+37.0 will only be possible with the measurement of spectroscopic redshifts for a large sample of member galaxies, which is already foreseen with VLT in our follow-up programme.

Our redshift results are consistent with the three clusters being part of the same supercluster structure, which will eventually lead to the formation of a more massive object ($\sim 10^{15} M_\odot$). This is also supported by our analysis of the galaxy population with SDSS data: the galaxy density maps show the presence of a possible population of inter-cluster galaxies, significant at 3$\sigma$, connecting the whole system (Fig. 7). However, the relaxed appearance of component $A$, its large distance ($2.6 \, \text{Mpc}$) in the plane of the sky from component $C$ and along the line of sight from component $B$, as well as the absence of any detectable excess X-ray emission between the components, may suggest that we are witnessing a very early phase of interaction.

Using the X-ray results from the new XMM-Newton observation, we built a multi-component model that we used to extract
the total SZ signal from Planck data. We compared the improved estimate of $Y_{SZ}$ with the prediction from X-rays and we found the latter to be about 68% of the measured SZ signal. The discrepancy between these two values is reduced with respect to Paper I and is not at the 1.2σ level.

The results from our simulations have shown that an offset as large as 5° can be expected in the reconstructed $y$-maps for low-significance objects, due to noise fluctuations and astrophysical contributions. With this study we have illustrated the expected difficulty of accurately reconstructing the two-dimensional SZ signal for objects with low signal-to-noise ratio. Indeed the instrumental noise and astrophysical contamination compete with the SZ effect at the detection limit threshold. Nonetheless, objects like PLCKG214.6+37.0 can be detected with a dedicated optimal filtering detection method, and the SZ signal can be reconstructed assuming priors (such as position, size, and relative intensity) from other wavelengths.

Despite a deep re-observation of this system with XMM-Newton, the intrinsic limitations of our X-ray data and of the current Planck SZ maps do not allow us, for the time being to assess the presence of possible inter-cluster emission.

A careful analysis of the galaxy dynamics in the complex potential of this object and of the mass distribution from weak lensing will both be available with our on-going optical follow up programme. These observations, combined with the results presented in this paper and with new Planck data obtained in two other full surveys of the sky, might lead to a deeper understanding of this triple system.
