Key words: immune system, mass spectrometry, inflammasome, protein secretion, innate immunity, T cell
ABSTRACT

Introduction: The immune system is our defense system against microbial infections and tissue injury, and understanding how it works in detail is essential for developing drugs for different diseases. Mass spectrometry-based proteomics can provide in-depth information on the molecular mechanisms involved in immune responses.

Areas covered: Summarized are the key immunology findings obtained with MS-based proteomics in the past five years, with a focus on inflammasome activation, global protein secretion, mucosal immunology, immunopeptidome and T cells. Special focus is on extracellular vesicle-mediated protein secretion and its role in immune responses.

Expert commentary: Proteomics is an essential part of modern omics-scale immunology research. To date, MS-based proteomics has been used in immunology to study protein expression levels, their subcellular localization, secretion, post-translational modifications, and interactions in immune cells upon activation by different stimuli. These studies have made major contributions to understanding the molecular mechanisms involved in innate and adaptive immune responses. New developments in proteomics offer constantly novel possibilities for exploring the immune system. Examples of these techniques include mass cytometry and different MS-based imaging approaches which can be widely used in immunology.
1. Introduction

Pathogens can rapidly adapt and evolve and thereby avoid detection by the human immune system. However, multiple defense mechanisms have developed to recognize and eliminate pathogens, including innate and adaptive cell-mediated immunity (Figure 1). The innate immune system is the first line of defense against microbial infections. It also responds to host factors that arise during tissue damage and metabolic dysregulation. Inflammasomes are multimeric cytosolic protein complexes that mediate innate immune responses to microbial infection, cellular damage, and metabolic dysregulation [1]. The assembly of inflammasomes triggers activation of inflammatory cysteine protease caspase-1 and proteolytic processing and secretion of pro-inflammatory cytokines Interleukin (IL)-1 and IL-18. These cytokines are important mediators of inflammatory responses and are critical in both local and systemic inflammation. Activation of innate immunity is essential to control infections and provide the necessary signals to trigger adaptive immunity [1].

Activation of adaptive immunity is usually required to completely eradicate microbial infections.

Protein secretion is an important part of the immune response. Proteins can be secreted through multiple pathways (summarized in Fig 2). According to the Human Protein Atlas [2], approximately 39% of the ~20,000 human protein-coding genes are
predicted either to express a signal peptide that is required for secretion through the ER/Golgi secretory pathway or to have at least one transmembrane region, suggesting active transport of the corresponding protein out of the cell. Proteins that lack a signal peptide can be secreted through unconventional, vesicle-mediated pathways. Immune cells secrete a wide range of proteins including immunomodulatory factors (e.g., cytokines and chemokines) that are indispensable for proper coordination of appropriate cellular responses.

Mass spectrometry (MS)-based proteomics can provide in-depth information about how the immune system is regulated and the molecular mechanisms involved in immune responses. The main goal of this review is to summarize the key findings in molecular immunology in the past five years using different MS-based proteomics approaches, with a focus on inflammasome activation, global protein secretion and extracellular vesicles, mucosal immunology, immunopeptidome and T cells. Key findings obtained with proteomics studies related to these topics are summarized in Table 1.

2. Proteomics contributes to immunology research at multiple levels

Modern MS-based proteomics methods give detailed spatio-temporal information on proteins on a global scale. Proteomics provides information on protein expression, sub-cellular localization, post-translational modifications (PTMs), and interactions. Most proteomics methods use a so-called ‘bottom up’ approach, where the proteins are first digested into peptides; the resulting peptides are analyzed by liquid chromatography (LC)-tandem mass spectrometry (MS/MS) followed by computational data analysis. Several methods are available for the identification and
quantification of thousands of proteins from biological samples and comparison of the proteome profiles of different samples (reviewed in [3,4]). Quantitative MS-based proteomics provides data on protein expression levels and also on protein localization and trafficking inside the cells when it is combined with sub-cellular fractionation. Several studies have used this approach to characterize changes in sub-cellular proteomes due to viral infection [5,6] and other stimuli activating innate immune responses [7,8]. In addition to global screening, MS-based proteomics provides methods for targeted protein quantification (reviewed in [9]).

Protein phosphorylation is a widely studied PTM with major impacts on most cellular signaling cascades. In phosphoproteomics, the phosphorylated peptides need to be enriched before the LC-MS/MS analysis. The two most common enrichment methods take advantage of titanium dioxide or immobilized metal ion affinity chromatography. Advances in phosphopeptide enrichment methods and MS analysis, together with improved data analysis tools, have made it possible to identify thousands of phosphoproteins from cellular samples (reviewed in [10,11]). Phosphoproteome studies on host responses to viral infection [12-16] have shown that viral infection alters the phosphorylation status of hundreds of proteins involved in pathways critical to the host response to infection. For example, phosphoproteome characterization of influenza A virus (IAV) infection in human macrophages, combined with bioinformatics and functional studies, showed that cyclin-dependent kinases are activated upon IAV infection; targeting these kinases with small-molecule inhibitors could be a novel strategy to treat severe influenza virus infections [13]. This study also highlights the importance of using primary cells in proteome-level studies to obtain the most novel and biologically meaningful data for further functional studies.
In addition to large-scale phosphoproteomic analysis, MS-based studies focusing on the detailed characterization of individual protein’s phosphorylation status have contributed to our understanding of immune system regulation. Very recently, Lee et al. used this approach to show that infection-specific phosphorylation of glutamyl-prolyl tRNA synthetase induces antiviral immunity [17]. In a very elegant study, Liu and co-workers used targeted quantification by MS to demonstrate that the adaptor molecules of the innate immunity, MAVS, STING, and TRIF are phosphorylated to mediate activation of transcription factor interferon regulatory factor 3 [18].

Proteins act in cells in complexes with other proteins, and in-depth knowledge of these complexes is essential to understand cellular signaling in detail. Affinity purification (AP) combined with MS is a widely-used strategy to characterize protein complexes. Several methods of AP are available and have been reviewed recently [19]. The AP-MS methods include traditional immunoprecipitation using a protein of interest as bait. The main drawback of this technically simple approach is the high background of proteins non-specifically binding to the antibody. Therefore, many approaches have been developed using two-step AP to maximize the recovery of specific interactions. AP-MS has produced significant new knowledge of key proteins involved in immune responses [20-24]. These include studies of 14-3-3 and Rab GTPase proteins. 14-3-3 proteins are a family of conserved regulatory molecules that can bind a multitude of functionally diverse signaling proteins through phosphorylation-dependent interactions. Öhman et al. [21] combined phosphoproteomics with quantitative 14-3-3 protein AP to characterize the 14-3-3 protein-mediated signaling pathways activated during cytosolic dsRNA-induced
innate immune responses in human keratinocytes. Through extensive bioinformatics analysis of the combined datasets combined with functional studies, they showed that sirtuin 1 and Rel A-associated inhibitor are novel regulators of antiviral innate immune responses. Rab GTPases regulate many stages of membrane traffic, including vesicle formation, vesicle movement, and membrane fusion. In a recent study, Li et al. [24] depicted the interactomic landscapes of major mammalian Rab GTPase family proteins in dendritic cells (DCs) and provided a global view of intracellular membrane organization in combination with AP-MS and imaging tools. Further analysis showed that the Rab32 subnetwork of proteins has anti-microbial functions.

3. Intracellular proteome characterization of inflammasome activation

Inflammasomes are critical components of the innate immune system that activate inflammation and contribute to the initiation and pathology of human disease in many ways. Inflammasomes are critical for the clearance of pathogens and damaged cells, but overwhelming inflammasome activation is a major driver of autoimmune disease and metabolic disorders [1]. The canonical inflammasome protein complexes consist of caspase-1, adapter protein apoptosis-associated speck-like protein containing a caspase-recruitment domain (ASC), and a sensor protein. These sensor proteins belong to NOD-like receptor (NLR) or to the absent in melanoma 2 (AIM2)-like receptor families and include NLRP1, NLRP3, NLRC4, and AIM2 inflammasomes[1]. Of these, NLRP3 inflammasome is the most extensively studied because of its activity in many human diseases, including autoinflammatory diseases, Alzheimer’s disease, atherosclerosis, and diabetes [25].
Several AP-MS-based studies have identified novel components and regulators of inflammasomes. A systematic proteomic screen for proteins that associate with DNA led to the identification of the AIM-2 inflammasome, which is involved in the cytoplasmic recognition of double-stranded DNA [26]. In addition, AP-MS resulted in the identification of end-binding protein 1 as a crucial component of the AIM-2 inflammasome [27]. Further, He and co-workers recently identified an essential mediator of NLRP3 activation called NIMA Related Kinase 7 (NEK7) using AP-MS [28]. NEK7 associates with NLRP3 following ATP stimulation and is required for NLRP3-mediated caspase-1 activation [28]. Imiquimod is a small-molecule ligand of Toll-like receptor-7 that is licensed for the treatment of viral infections and skin cancers. It is also a known activator of NLRP3 inflammasome in myeloid cells [29]. A recent study used AP-MS with a bead-coupled imidazoquinoline to identify the targets of imiquimod [30]. These results show that imiquimod inhibits the quinone oxidoreductases NQO2 and mitochondrial Complex I. This resulted in reactive oxygen species formation and thiol oxidation and was followed by NLRP3 activation via NEK7. AP-MS-based techniques have also been exploited to study the post-translational regulation of inflammasome activation: Yan et al. showed that dopamine inhibits NLRP3 inflammasome activation via a second messenger cyclic adenosine monophosphate that binds to NLRP3 and promotes its ubiquitination and degradation via the E3 ubiquitin ligase MARCH7 [31].

In addition to canonical inflammasomes, non-canonical inflammasomes have recently been described [32]. Non-canonical caspase-4/5 inflammasome activates pyroptosis, an inflammatory form of cell death in response to infections of gram-negative bacteria [62]. Human non-canonical caspase-4/5 inflammasome can also activate the
canonical NLRP3 inflammasome by an unidentified mechanism [33]. The AP-MS approach identified a new component of the inflammasomes called gasdermin D [34]. Gasdermin D is required for pyroptosis in response to both NLRP3 inflammasome and non-canonical inflammasome activation [25].

Quantitative proteomics has also produced new knowledge on the inflammasomes. Worah and co-workers utilized label-free quantitative MS to identify differences between the proteome profiles of primary human DC subsets. They showed that plasmacytoid DCs do not express caspase-1, the central component of canonical inflammasomes, and that they also express other inflammasome-related proteins at low levels [35]. This suggests that the role of plasmacytoid DCs is not related to inflammasome-mediated secretion of pro-inflammatory cytokines: instead, they are potent producers of antiviral type I interferons [36].

4. Secretome analysis of immune cells

Protein secretion through multiple pathways is an important part of immune responses. In immunology, studies in protein secretion have focused mostly on analyzing secretion of cytokines and chemokines using antibody-based assays such as ELISA. However, recent system-level characterizations using MS-based proteomics approaches have shown that immune cells activate a much more global protein secretion than just secretion of cytokines and chemokines. The global pattern of secreted proteins (secretome) of a cell depends largely on its activation state; the detailed characterization of secretomes provides valuable information for understanding immune response mechanisms. At present, high-resolution MS combined with advanced sample preparation methods allows for analysis of the total
secretome from low numbers of cells: Meissner and co-workers were able to achieve low picogram sensitivity by quantifying the time-resolved release of 775 proteins from as little as 150,000 stimulated mouse macrophages per condition [37]. This study linked specific secretory profiles to the activation of distinct intracellular signaling adaptor proteins and demonstrated that the secretions of many pro-inflammatory mediators have redundant mechanisms, leading to a potentially vast increase in their secretion.

Total secretomes of human cells upon virus infection have been widely studied with the rationale of understanding the cellular response to the infection, elucidating the physiopathology of the resulting disease as well, and determining potential therapeutic targets. Global secretome analysis of human macrophages after infection by IAV [5] and herpes simplex virus [38] revealed massive release of danger signal proteins and identified secreted host factors that have a role in antiviral defense. In addition to viral infection, the secretomes of human macrophages have been studied following different stimuli [39-41]. These include ATP, monosodium urate (MSU) and β-glucans. Extracellular ATP and MSU are endogenous danger signals known to activate inflammatory responses; β-glucans are the main constituents of fungal cell walls, triggering an effective innate immune response. The secreted proteins identified in these studies involved many danger signal proteins that amplify inflammatory response during innate immune activation, such as annexins, high mobility group proteins and S100 and heat shock proteins. Bioinformatic characterization of these secretomes revealed that most identified proteins did not have the signal sequence required for classical ER/Golgi-mediated secretion and that
most of the proteins are found in the ExoCarta database, having been identified in the exosomes of multiple organisms [42].

The effects of bacterial infection on the secretome of several human cell types have also been investigated with proteomic tools. For example, total secretome analysis revealed strong differences in the inflammatory responses induced by different *Staphylococcus aureus* strains [43]. Uhlmann and colleagues identified a novel secreted streptococcal factor that can potentially trigger neutrophil activation and degranulation during *Streptococcus pyogenes* infections of human neutrophils [44]. In addition to live bacteria, secretome analysis has been performed in cells that have been activated with lipopolysaccharide (LPS), the cell wall component of gram-negative bacteria. Secretome analysis of endothelial cells stimulated with extracellular LPS to activate Toll-like receptor (TLR)4 led to the discovery of 19 potential biomarkers for sepsis [45]. Most secreted proteins induced by LPS stimulation were related to the regulation of actin cytoskeleton [45].

Secretome analysis of human adipose tissue-derived mesenchymal stem cells (hASCs) revealed secretion of several chemokines and cytokines in response to stimulation with tumor necrosis factor (TNF), a key pro-inflammatory cytokine [46]. This demonstrated that TNF-treated hASCs secrete factors that drive the monocyte migration and subsequent tissue regeneration. Oh and co-workers performed secretome analysis of human monocytes from newborn and elderly donors stimulated with several commonly used adjuvants [47]. These adjuvants activate an innate immune response, typically via TLR stimulation. TLR-mediated immune responses show distinct differences between different age groups, and the study
demonstrated that adjuvants induce different yet partially overlapping secretomes that vary with the adjuvant types and the age of the study participants. These data are important when designing vaccines for certain age groups.

5. **Proteome analysis has shown that extracellular vesicles play an important role in immune responses**

Proteins that do not carry an N-terminal signal peptide required for the classical ER/Golgi secretory pathway are released unconventionally. They are packed into various types of membrane-enclosed structures, collectively called “extracellular vesicles” (EVs) [48]. These EVs include microvesicles (MVs) that bud directly from the plasma membrane and are shed into the extracellular space, exosomes that are formed when multivesicular bodies fuse with the plasma membrane, and other vesicles whose origin has been linked with different cellular processes including secretory autophagy, apoptosis and lysosome secretion. EVs are released from virtually all cell types for long-distance intercellular communication, carrying a diverse and well-protected cargo of biomolecules: proteins, nucleic acids, and bioactive lipids. They can travel considerable distances throughout human body fluids and tissues and deliver molecular information to recipient cells upon endocytosis. When released from stimulated cells, they have been shown to modulate the immune response [49].

Proteomics has been used extensively for the characterization of EVs released from immune cells. For proteomics analysis, EVs are isolated from a multitude of biological fluids and growth media using different protocols involving high-speed centrifugation, affinity purification, precipitation, and filtration-based methods. For example, Groot Kormelink and co-workers used high-speed ultracentrifugation to isolate EVs from
mast cells following immunoglobulin E-mediated cell activation. They established that during their degranulation mast cells release EVs containing mast cell-specific proteases and concluded that these EVs and their content are potentially important immune regulators [50]. Another proteomic study utilizing similar EV isolation method showed that foam cells, which are fat-laden macrophages in atherosclerotic plaques, secrete more EVs than unstimulated macrophages. These foam cell-derived EVs promote vascular smooth muscle cell migration and adhesion and potentially play a role in the disease progression [51]. The optimal methods for isolation and separation of different EVs are still highly debated [52]. A recent study by Kowal and colleagues provided an extensive characterization of proteins in different EV classes secreted from human DCs. They first purified different EVs by their sedimentation speed and then either by their behavior upon upward floatation into iodixanol gradients or by immuno-isolation. Based on quantitative proteome analysis of separated EV populations, they suggest novel protein markers to distinguish different EV populations [53].

5.1 EVs secreted during microbial infection

Proteomic analyses of EVs released from virally infected cells have been performed with the purpose of understanding the observed overlap between natural endocytosis-exocytosis pathways and the virus life cycle. Accumulating evidence for viral hijacking of human EV secretory pathways and membranes raised the hypothesis of the existence of “Trojan exosomes,” as carriers of viral genetic material, facilitating viral infections [54]. Consequently, identification of EV proteins directly associated with virus dissemination is of interest for the identification of novel drug targets and development of antiviral therapies.
Several groups applied proteomics to analyze the EVs from human immunodeficiency virus (HIV)-1-infected cells. Li and colleagues revealed that EVs released from HIV-1-infected H9 cells contain a unique and quantitatively different protein signature than exosomes released from uninfected cells and harbor regulatory molecules that impact the processes of cellular apoptosis and proliferation [55]. This study also showed that EVs facilitate the transfer of HIV-1 and viral constituents from infected macrophages to neighboring uninfected cells [56]. Meckes et al. performed a large-scale quantitative proteomic study, infecting eleven B cell lines with Kaposi sarcoma-associated virus and Epstein-Barr virus or with both viruses and purifying the secreted EVs. This study demonstrated that viral infection causes virus- and host cell-specific modifications of the proteome of secreted EVs that is correlated with and dependent on the expression of viral oncogene latent membrane protein-1. This discovery not only shed new light on the roles of EVs in the pathogenesis of these common viruses but also identified immune regulatory pathways affected by the EVs that directly facilitate virus survival and spreading [57]. By applying an SILAC quantitative proteomics approach, Zhao and colleagues revealed that hepatitis B virus also alters the proteomic composition of hepatic cell line Huh-7-derived EVs [58]. A similar modulation was observed in the case of human T cell lymphotropic virus-infected T cell lines [59].

A recent article described the proteomic characterization of EVs released from human macrophages upon IAV infection [60], showing a robust EV-mediated protein secretion as early as 9 h post-infection. Proteins secreted in response to IAV infection included many proteins involved in translation, such as components of
spliceosome machinery and the ribosome. The data also shows that EVs derived from IAV-infected macrophages contain antiviral cytokines, fatty acid-binding proteins, copper metabolism Murr-1 domain proteins, and autophagy-related proteins. These data suggest an important role for EVs in intercellular communication during IAV infection.

Some of the most extensively studied EVs in the context of host cell-bacteria interaction involve those released from *Mycobacterium tuberculosis*-infected human macrophages. Hare *et al.* demonstrated that EVs from infected macrophages contain several interferon-inducible proteins [61]. Wang *et al.* compared the proteomic composition of EVs from *Mycobacterium avium*-infected macrophage-like THP1 cells. *M. avium* infection significantly changed the protein composition of exosomes isolated from THP-1 cells [62]. Exosomes isolated from infected cells contained components that induced immune responses in resting cells, suggesting an important function for exosomes in anti-mycobacterial host defense.

In addition to viral and bacterial infections, the role of fungal infection on EV secretion and composition has also been studied. Cypryk and co-workers showed that the major components of fungal cell walls, β-glucans, enhance vesicle-mediated protein secretion in human macrophages. The unconventionally secreted proteins included several receptors, such as cation-dependent mannose-6-phosphate receptor, macrophage scavenger receptor, P2X7 receptor, and several integrins [63]. A recent study of EVs from *C. albicans*-infected THP1 cells indicated that fungal stimulation induces secretion of EVs with alternated content of several signaling proteins.
including chitinase-3-like protein 1, which has been proposed as the component responsible for the pro-inflammatory properties of the secreted EVs [64].

5.2 Inflammasomes and EV secretion

The NLRP3 inflammasome activates caspase-1 and the subsequent secretion of pro-inflammatory cytokines in response to microbial infection and endogenous danger signals. A study utilizing iTRAQ-labelling-based quantitative proteomics linked caspase-1 to unconventional protein secretion as early as 2008 [65]. Subsequent proteomics studies showed that NLRP3 activators including ATP, β-glucans, and monosodium urate activate robust unconventional vesicle-mediated protein secretion in human macrophages [39-41,63]. In contrast to these inflammasome activators, LPS-induced TLR4 triggering did not result in EV-mediated protein secretion despite the fact that TLR4 signaling resulted in a strong activation of gene expression [41]. Active forms of the lysosomal proteases cathepsins were identified in EVs after NLRP3 inflammasome activation [40,41]. Cathepsins are proteases that are required for NLRP3 inflammasome activation. This suggests that EVs released during inflammasome activation can amplify and/or activate NLRP3 inflammasome in recipient cells. In line with these results, Zhang and co-workers have shown that nigericin, a known activator of the NLRP3 inflammasome, activates EV-mediated protein secretion from LPS-primed macrophages [66]. They identified several Toll-like receptors, as well as components of the NF-κB and NLRP3 inflammasome signaling pathways, in EVs isolated from LPS-primed and nigericin-activated mouse macrophages. These results also suggest that EVs isolated from macrophages after NLRP3 inflammasome activation can enhance inflammatory responses in recipient cells.
A recent study showed that, in addition to NLRP3 inflammasome, also the non-canonical caspase-4/5 inflammasome can activate unconventional vesicle-mediated protein secretion in human macrophages [67]. The proteins secreted through EV-mediated pathway contained ribosomal and danger signal proteins, including TLR4-ligands S100A8 and prothymosin-α which may contribute to endotoxic shock during non-canonical inflammasome activation.

6. Proteomics to study mucosal immunology

Mucosal immunology is in the front-line status within the immune system preventing the uptake of pathogens and other foreign materials. Proteomics has been used to study mucosal specimens during microbial infection [68]. A label-free quantitative MS was used to study specimen isolated from small intestine of patients with acute and convalescent stages of Vibrio cholerae infection. This study identified 27 host proteins that were differentially abundant between the acute and convalescent stages of infection. The majority of these proteins had known roles in innate immunity including cytokine production and apoptosis. The authors conclude that a strong inflammatory response is generated in the gut mucosa early after onset of V. cholerae infection, which may be critical for the development of long-term immunity against V. cholerae [68].

Proteomics has also been used to identify disease mechanisms and novel biomarkers and from mucosal colon biopsies for inflammatory bowel disease (IBD) including Crohn’s disease (CD) and ulcerative colitis (UC) [69-73]. Accurate differentiation between new onset CD and UC is demanding and therefore novel
biomarkers are needed. Similarly, differentiation of CD and intestinal tuberculosis (ITB) is challenging. Starr et al. used SILAC to analyze mucosal biopsies from 99 pediatric control and biopsies of patients with CD and UC. The study identified two panels of candidate biomarkers for the diagnosis of IBD and the differentiation of IBD subtypes [71]. Rukmangadachar and co-workers analyzed colonic biopsies from inflamed mucosa of treatment-naïve patients with ITB, CD and controls with iTRAQ. This study concludes that there are differentially expressed proteins in tissue proteome of CD and ITB but fails to identify biomarkers that could be used to differentiate these diseases. Bennike and co-workers analyzed mucosal colon biopsies from non-inflamed tissue of patients with UC and compared the proteomes of those samples with the samples taken from healthy controls with label-free quantitative MS-based proteomics. Proteins with increased abundances in the UC colon biopsies included proteins associated with neutrophil extracellular traps and proteins functioning in innate immunity [71]. These results suggest a role for innate immunity in the etiology of UC. Mottawea et al. found altered host proteome in new-onset pediatric patients with DC [73]: especially mitochondrial proteins implicated in H\textsubscript{2}S detoxification were expressed at low level. At the same the relative abundance of H\textsubscript{2}S microbial producers was increased and dysfunctional host mitochondrial function was observed. The study shows that host-microbiota interactions are disturbed in CD and provides a new mechanistic explanation for the pathogenesis of CD [73].

7. Proteomic characterization of the immunopeptidome

The immunopeptidome is the collection of peptides associated with and presented by major histocompatibility complex (MHC) molecules. Characterization of these
peptides is important for the development of better vaccines and immunotherapies against autoimmunity. The MHC immunopeptidome is highly complex and MS-based approaches have proven to be the method of choice in these studies (reviewed in [74]). At present, most immunopeptidome studies utilize affinity column coupled with monoclonal antibody (mAb) specific for a certain MHC class or allotype followed by MS-analysis of the captured peptides.

Several recent studies have shown that it is possible to identify thousands of HLA-bound antigenic peptides from diverse biological samples using this approach. The samples include celiac disease-associated MHC molecules, different cancer cell lines, fibroblasts, DCs, macrophages, and bronchoalveolar lavage (BAL) from patients with sarcoidosis [75-79].

PTMs are an additional source of complexity in the immunopeptidomes. So far, phosphorylated and arginine methylated HLA-bound peptides have been identified [80,81]. These modifications potentially provide a unique source of disease-related MHC peptides that can elicit specific immune responses which may offer a novel targets for immunotherapy.

The analyses of immunopeptidomes have usually been done using large amount of starting material not feasible to obtain from clinical samples. Heyder et al. optimized the method to identify HLA-DR-bound peptides from low cell numbers and utilized it to study BAL cells obtained from patients with sarcoidosis [78], and showed that the investigation of the BAL immunopeptidome from individual patients and healthy controls is possible with MS-based methods in order to identify disease-associated peptides. Moreover, a very recent report by Bassani-Sternberg et al. showed that advanced MS can be used directly for identification of mutated peptide ligands isolated from HLAs on the surface of native tumor tissues and concluded that these
mutated peptide ligands yield true neoepitopes with high relevance for immunotherapeutic strategies in cancer [82]. The proteasome generates the epitopes presented on HLA class I molecules that elicit CD8+ T cell responses. The key step for the transformation of a protein into an HLA-I–restricted epitope is usually processed by the proteasome, which cuts proteins into peptides; alternatively, the proteasome can also cut and paste peptide sequences, thereby releasing peptide antigens that do not correspond to the original protein sequence. However, this proteasome-catalyzed peptide splicing has long been considered to occur only rarely. Liepe et al. developed an MS-based strategy to analyze this and unexpectedly revealed that a large fraction of HLA class I ligands are proteasome-generated spliced peptides [83]. Such merged peptides might turn out to be useful in vaccine or cancer immunotherapy development.

8. Proteomic studies on T cells
T cells play a central role in adaptive, cell-mediated immunity; their action is usually required for the final eradication of a microbial infection. Proteomics has been applied extensively to characterize T cells. Early quantitative MS-based proteomics studies on human primary CD4+ T helper (Th) cells revealed proteome changes in both microsomal and nuclear fractions [84-86]. These include the regulation of several immune-related proteins, including galectin-1, small GTPases GIMAP1 and GIMAP4, and SATB1, during Th cell differentiation. Recently, the proteomes of human Th1 and Th1/Th17 clones derived from intestinal biopsies of Crohn's disease patients were characterized using high-resolution MS [87]. In total, more than 7,000 proteins from the Th1 and Th1/Th17 clones were identified, with 334 proteins being differentially
expressed. Major differences were observed for cytotoxic proteins that were overrepresented in the Th1 clones.

CD8+ cytotoxic T cells (CTLs) have also been characterized using quantitative proteomics [88,89]. Hukelmann et al. used high-resolution MS to map the proteome of CTLs and quantify the regulatory effect of selective inhibition of the mammalian target of rapamycin complex 1 (mTORC1) and combined inhibition of mTORC1 and mTORC2 on CTL proteomes. They identified almost 7,000 proteins from CTLs, demonstrating the diversity of the CTL proteome and how mTOR inhibitors control T cell function and program T cell signal-transduction pathways [88]. Böttcher et al. used transcriptome and proteome profiling of different memory CD8+ cell populations to demonstrate that CX3CR1 is superior for classification of these cell populations [89]. This analysis allowed the authors to establish a core gene and protein signature shared by memory CD8+ cells with a cytotoxic function independent of their tissue localization. The results will help establish better immune monitoring that will improve guidance of immune therapies.

Navarro et al. used targeted proteomics, namely, selected reaction monitoring (SRM), to quantify PKD2 abundance in naïve CD8+ T cells [90]. PKD2 is a serine and threonine kinase that is activated in T cells by diacylglycerol and protein kinase C in response to stimulation of the T cell receptor (TCR) by an antigen. They quantified the activation of PKD2 at the single-cell level and found that this kinase acts as a sensitive digital amplifier of TCR engagement. SRM can yield absolute quantification of target peptides from a particular protein in a complex sample. In principle, it also has the potential to detect proteins in the low-attomole range of abundance.
Several phosphoproteome studies on T cell lines have aimed to dissect IL-2- and IL-15-induced cell signaling events. In these studies, Osinalde and co-workers utilized SILAC labeling and high resolution MS combined with phosphotyrosine immunoprecipitation [91-93] and TiO2 enrichment of the phosphopeptides [94,95] to demonstrate that the signaling pathways activated by IL-2 and IL-15 are very similar [94,95]. In addition, they combined antibody- and TiO2-based enrichment with SILAC labeling before MS analysis to show that serine/threonine phosphorylation of the scaffold protein Gab2 is an important step in regulating IL-2 signaling [96].

Quantitative phosphoproteomics has also been used to characterize CD8+ CTLs in detail [97,98]. Ross and co-workers showed that CTLs contain an IL-2-induced JANUS kinase independent signaling network. This SRC family tyrosine kinase-controlled signaling network regulates 10% of the CTL phosphoproteome and critically contributes to CTL function [97].

In addition to protein phosphorylation, TCR-induced ubiquitination is known to regulate the function of T cells. More specifically, the function of T cells is negatively regulated by the E3 ubiquitin-protein ligases CBL and CBLB. Voisinne et al. utilized AP-MS to analyze the dynamics of the CBL and CBLB signaling complexes formed after TCR stimulation [99]. They identified several proteins that had not yet been implicated in those signaling complexes and demonstrated that the CD5 transmembrane receptor constitutes a key scaffold for ubiquitin-ligase mediated ubiquitylation following TCR engagement [99]. These results provide a molecular basis for understanding the negative regulation of TCR signaling.
Cluster of Differentiation 28 (CD28) is a protein expressed on T cells that provides co-stimulatory signals required for T cell activation and survival. Roncagalli et al. combined AP-MS analysis and mouse functional genomics to determine the mode of action of RLTPR cytosolic protein, also known as CARMIL2, which is essential for CD28 co-stimulation in mouse T cells. They developed mice that bear a genetic tag allowing for AP-MS analysis of the RLTPR interactome in primary T cells, showed that RLTPR acts as a scaffold, bridging CD28 to the CARD11/CARMA1 cytosolic adaptor and to the NF-κB signaling pathway, and identified previously unknown proteins in the CD28 signaling pathway [100].

9. Expert commentary
Proteomics is an essential part of modern life science research. Proteome-level information is needed to elucidate disease mechanisms, find new drug targets, and develop personalized medicines. To date, MS-based proteomics has been used in immunology to study protein expression levels, their subcellular localization, post-translational modifications, and interactions in immune cells upon activation by different stimuli. These studies have contributed significantly to our understanding on the molecular mechanisms involved in both innate and adaptive immune responses (Table 1).

Post-translational modifications affect protein activity; sub-cellular localization also has a key impact on understanding the molecular mechanisms involved in immune responses in detail. Information about PTMs is also important for drug discovery. So far, most of the focus has been on phosphoproteome analysis, mainly because the techniques for these studies are already well established. However, the importance of other modifications is being increasingly appreciated, and previously
uncharacterized modifications are frequently being discovered. In innate immunity, the cross-talk between protein phosphorylation and ubiquitination is an emerging topic [101,102]. Other, less well-studied PTMs that modulate innate immunity are acetylation, glutamylolation, and deamidation [102]. A main challenge for PTM analyses is that they usually require that the modified peptides are enriched from the total peptide pool before MS-analysis, and enrichment methods for different PTMs are newly established. Additionally, MS data analysis is more challenging than the analysis required for protein identification and quantification. However, the methods for both of these are actively being developed; it is likely that many new tools to facilitate these analyses will arise in the next five years.

Global proteome studies of secretomes and EVs have shown that unconventional, vesicle-mediated protein secretion is an essential part of immune responses. Most proteome studies of protein secretion have focused on protein identification and quantification. In addition to intracellular PTMs, there are some reports on protein modifications in EVs; it will be important to characterize these PTMs from EV proteins in more detail in the future [103,104]. Proteome studies have also highlighted the fact that vesicle-mediated protein secretion is activated upon canonical NLRP3 and non-canonical caspase-4/5 inflammasome activation. Future proteome studies are needed to reveal novel components and regulators of the non-canonical caspase-4/5 inflammasome.

An important proteomic technique to elucidate intracellular signaling pathways is AP-MS. This method has revealed several critical components and regulators of the inflammasomes. In AP-MS, the typical workflow includes one- or two-step affinity
purification of the protein complex followed by MS-based identification and quantification of proteins in the complex. The starting material is most often the total cellular lysate; the method requires that false-positive interactions are minimized as efficiently as possible, both during sample preparation and in data analysis after MS-analysis.

Additionally, several targeted MS-based approaches have been developed that allow for MS-based monitoring of a set of pre-selected proteins from complex mixtures. In these methods, the proteins of interest do not need to be purified from the sample; the selection of the proteins to be measured and quantified is performed in the MS workflow. These methods can be used in immunology to complement traditional antibody-based assays such as western blotting and ELISA. The main advantages of these assays are that they are not dependent on the available antibodies and that they can be fully automated.

10. Five-year view
MS-based proteomics has made major contributions to understanding the molecular mechanisms involved in immune responses. New developments in proteomics constantly provide novel possibilities for advanced proteome analysis. Examples of novel proteomics techniques that will most likely be used widely in proteomics include mass cytometry and different MS-based imaging approaches. Mass cytometry enables high-dimensional, single-cell analysis of cell type and state. It combines the cellular analysis principles of traditional fluorescence-based flow cytometry with the
selectivity and quantitative power of inductively coupled plasma-mass spectrometry; multiplexing of up to 40 independent measurements on a single cell is possible [105,106].

Creating proteome maps is exemplified by a study of Marakalala et al.: they combined laser-capture microdissection, high resolution MS, and confocal microscopy to generate detailed molecular maps of human granulomas that are the pathological hallmark of tuberculosis [107]. They showed that the centers of granulomas have a pro-inflammatory environment characterized by the presence of antimicrobial peptides, reactive oxygen species and pro-inflammatory eicosanoids; conversely, the tissue surrounding the caseum has a comparatively anti-inflammatory signature. Based on the protein and lipid snapshots obtained, they hypothesize that the pathologic response to *M. tuberculosis* is shaped by the precise anatomical localization of these inflammatory pathways during the development of the granuloma.

The proteome of blood immune cells has been extensively investigated; however, so far, there is little data on tissue-resident immune cells. Very recently, Holzlechner et al. [108] characterized these cells in colon tissue, which exhibited a strong infiltration of immune cells. They used MALDI MS-imaging (MALDI MSI) and showed for the first time that it is well-suited for visualizing the spatial distribution of immune cells in human colon tissue. The MALDI MSI technique has vast potential for use in rapid investigations of tissue-specific features of cells in the future.

At present, the fundamental importance of proteomics in all life science research is well recognized. The participants of the National Institutes of Health Workshop in
Clinical Proteomics in 2012 concluded that ‘deeper understanding of the human proteome could help fill in the gaps between genomes and phenotypes, transform the way we develop diagnostics and therapeutics, and thereby enhance overall biomedical research and future healthcare’ [109]. Additionally, the current methods allow for deeper and faster proteome characterization than what has ever been possible before. However, proteomics is still not routinely used in most immunology research groups. This is due to two main reasons: proteomics techniques are not always easily accessible to biomedical researchers, and more education is needed for biomedical students and researchers so they understand how proteomics could contribute to their research. As early as 2008, one of the leading pioneers in MS-based proteomics, professor Matthias Mann, argued that the true integration of proteomics technology into molecular biology laboratories could be a paradigm shift for all of biology and biomedicine, but quantitative proteome measurements need to become as accessible and convenient as western blots are now for this to happen; equally important, proteomics should be incorporated into biology education [110].

Another key issue for implementing proteomics into immunology and other biomedical research is the seamless collaboration of researchers from multiple disciplines (immunology, proteomics, and bioinformatics).

**Key issues**

- Proteomics can provide detailed information on cellular signaling mechanisms involved in immune responses; MS-based proteomics has made important contributions to understanding the human immune system in more detail
- Developments in MS-based proteomics during the last decade have enabled deeper and more rapid proteome analysis than what has previously been
possible; with current methods, it is possible to identify, quantify, and characterize thousands of proteins in a single experiment

- MS-based proteomics techniques have been applied extensively to characterize T cells and immunopeptidomes
- Phosphoproteomics has shown that the functions of key receptors and adaptor molecules of the innate immune system are regulated by phosphorylation
- Proteomics has revealed several novel components and regulators of inflammasomes
- Global protein secretion analyses have shown that vesicle-mediated protein secretion plays an important role in innate immune responses
- Proteomics techniques develop constantly and MS-based imaging methods will offer important new possibilities for immunological studies
- To make full use of the power of proteomic techniques, true integration of this technique into immunology laboratories and close collaboration between immunology, proteomics and bioinformatics researchers are needed

The authors have received support from the University of Oslo and the University of Helsinki.

**Declaration of interest**
The authors have no relevant affiliations or financial involvement with any organization or entity with a financial interest in or financial conflict with the subject matter or materials discussed in the manuscript. This includes
employment, consultancies, honoraria, stock ownership or options, expert
testimony, grants or patents received or pending, or royalties.

Figure legends

Figure 1. Innate immunity is required for the activation of adaptive T cell-mediated
immunity. Macrophages and dendritic cells (DCs) are central effector cells of innate
immunity; their pattern recognition receptors (PRRs) detect the presence of pathogens and
endogenous danger signals. This recognition results in the activation of innate immune cells.
Macrophages and DCs start to secrete cytokines to mount an inflammatory response,
chemokines to recruit other immune cells to the site of infection or inflammation, and other
proteins inducing anti-microbial defense and tissue regeneration. Activation of
inflammasomes, which are PRRs expressed by macrophages and DCs, triggers the
secretion of IL-1 family cytokines and unconventional protein secretion in general. Activated
innate immune cells also express co-stimulatory molecules, including cluster of differentiation
(CD) 80 and CD86, on their surface which makes antigen presentation to T cells possible.
Antigens are presented to T cells through the human leukocyte antigen (HLA) system, which
is a gene complex encoding the major histocompatibility complex (MHC) proteins in humans.
HLAs corresponding to MHC class I present peptides from inside the cell. This typically
occurs during viral infections, resulting in the activation of cytotoxic T cells that kill virus-
infected cells. HLAs corresponding to MHC class II present antigens from outside of the
innate immune cell to T cells. These particular antigens stimulate T helper cell activation,
which in turn stimulates B cell antibody production against the specific antigen.
Figure 2. Protein secretion mechanisms in immune cells. A fraction of the secreted proteins contain an N-terminal signal sequence and are secreted by the classical (ER/Golgi) secretory route. However, most of the proteins are secreted by unconventional means: an ATP-dependent ABC transporter-assisted route, incorporation into extracellular vesicles (secretory lysosomes, exosomes and microvesicles) or bypassing Golgi. Additional mechanisms or combinations of different pathways of secretion probably exist, as signal sequence-containing proteins are also abundantly found on EVs. **Immunopeptidomes**
Identification of celiac disease-relevant T cell epitopes. The approach presented is relevant for epitope identification in other MHC class II-associated disorders. Investigation of the bronchoalveolar lavage cells immunopeptidome from individual patients and healthy controls in order to identify disease-associated peptides. Large fraction of HLA class I ligands are proteasome-generated spliced peptides which could be useful in vaccine or cancer immunotherapy development.

**T cells**

GIMAP family proteins 1 and 4 are differentially regulated during human T helper cell differentiation. Gut-derived Th1 and Th1/Th17 clones have major differences in the expression of cytotoxic proteins. Detailed map of the cytotoxic T lymphocyte (CTL) proteome and the effect of the metabolic checkpoint kinase mTORC1 on CTLs. Also shows how mTOR inhibitors control T cell function and program T cell signal-transduction pathways. IL-2 signaling is both JAK-kinase-dependent and independent in CD8-positive T cells. CD5 transmembrane receptor constitutes a key scaffold for E3 ubiquitin-protein ligases following T cell receptor stimulation.

* AP-MS = affinity purification combined with mass spectrometry to identify protein complexes

iTRAQ = isobaric tags for relative and absolute quantification

GeLC-MS/MS = protein separation by SDS-PAGE and identification by MS

SILAC = stable isotope labeling in cell culture

ICAT = isotope-coded affinity tags

MALDI-TOF and nano-LC–MS/MS analysis to identify MHC peptides

optimized AP-MS to identify HLA-DR-bound peptides from low cell numbers

two-dimensional peptide prefractionation strategy followed by MS analysis
