Measurement of the $\Lambda_0^0$ Lifetime in $\Lambda_0^0 \to \Lambda_+^0\pi^-$_{Decays in $p\bar{p}$ Collisions at $\sqrt{s} = 1.96$ TeV

We report a measurement of the lifetime of the $\Lambda^0_b$ baryon in decays to the $\Lambda^0\pi^-$ final state in a sample corresponding to 1.1 fb$^{-1}$ collected in $pp$ collisions at $\sqrt{s} = 1.96$ TeV by the CDF II detector at the Tevatron collider. Using a sample of about 3000 fully reconstructed $\Lambda^0_b$ events we measure $\tau(\Lambda^0_b) = 1.401 \pm 0.046$ (stat) $\pm 0.035$ (syst) ps (corresponding to $c\tau(\Lambda^0_b) = 420.1 \pm 13.7$ (stat) $\pm 10.6$ (syst) $\mu$m, where $c$ is the speed of light). The ratio of this result and the world average $B^0$ lifetime yields $\tau(\Lambda^0_b)/\tau(B^0) = 0.918 \pm 0.038$ (stat and syst), in good agreement with recent theoretical predictions.

In the decays of beauty to charm hadrons the fundamental force underlying the decay of a b quark to a c quark is the weak interaction. However, the heavy b quark is surrounded by a cloud of light quarks and gluons so the strong interaction must be taken into account. In the limit of an infinite mass of the b quark, the heavy quark decouples from the light degrees of freedom. For a finite $m_b$, the decay rates can be computed as a series expanded in the small parameter $\Lambda_{QCD}/m_b$, where $m_b$ is the mass of the b quark and $\Lambda_{QCD}$ is the energy scale of the QCD interactions within the hadron. This is known as the heavy-quark expansion (HQE) \cite{1}. The application of HQE to the decays of the $L^0_b$ baryon ($udb$) and the beauty mesons ($B^0, Bd, B^+, br$) does not result in an identical series. For example, in the $(\Lambda_{QCD}/m_b)^3$ term $W$-boson exchange contributions are quite different \cite{2}, leading to a prediction of $\tau(L^0_b)/\tau(B^0) \neq 1$. Experimental studies of beauty hadron lifetimes therefore help us to test the theoretical understanding of the HQE series, and consequently the underlying QCD physics.

Over the past five years theoretical predictions of the lifetime ratio $\tau(L^0_b)/\tau(B^0)$ have not agreed with experimental values. In 2004 an HQE calculation including $O(1/m_b^3)$ effects resulted in $\tau(L^0_b)/\tau(B^0) = 0.86 \pm 0.05$ \cite{3}. This was in good agreement with the 2006 experimental world average of 0.804 ± 0.049 \cite{4}. In 2006 the CDF collaboration reported a measurement \cite{5} of the $L^0_b$ lifetime in the $L^0_b \to J/\psi L^0$ channel such that $\tau(L^0_b)/\tau(B^0)$ differed by $+2\sigma$ from the 2006 world average \cite{4}, was significantly higher than the 2004 HQE calculation \cite{3}, but was compatible with earlier HQE predictions \cite{6}. A more recent measurement by the DO collaboration \cite{7} in the same channel leads to a value of $\tau(L^0_b)/\tau(B^0)$ which is compatible with both the 2006 world average \cite{4} and the CDF value \cite{5}.

In this paper we present the first measurement of the $L^0_b$ lifetime in a fully hadronic final state. The data sample is produced in $p\bar{p}$ collisions at $\sqrt{s} = 1.96$ TeV at the Tevatron and corresponds to an integrated luminosity of 1.1 fb$^{-1}$. We reconstruct $L^0_b$ in the $L^0_b \to L^+ \pi^- \pi^-$ decay channel where $L^+ \pi^- \pi^-$ subsequently decays as $L^+_c \to pK^-\pi^+$. Throughout the paper, reference to a specific charge state also implies the charge conjugate state.

The components of the CDF II detector \cite{8} most relevant for this analysis are the tracking system and the displaced vertex trigger system. The tracking system lies within a uniform axial magnetic field of 1.4 T. The inner tracking volume is instrumented with either 6 or 7 layers of double-sided silicon microstrip detectors up to a radius of 28 cm from the beamline \cite{9}. These surround a layer of single-sided silicon mounted directly on the beam pipe at a radius of 1.5 cm \cite{10}. This system provides an excellent resolution (about 40 µm) on the impact parameter ($d_0$), which is defined as the distance of closest approach of the charged particle to the $p\bar{p}$ interaction point in the plane transverse to the beam direction. The $d_0$ resolution of 40 µm includes an approximate 30 µm contribution from the uncertainty of the interaction point in the transverse plane (added in quadrature). The outer tracking volume contains an open-cell drift chamber (COT) up to the radius of 137 cm \cite{11}.

CDF II employs a three-level trigger system. The extremely fast tracker (XFT) \cite{12} at the first level groups COT hits into tracks in the transverse plane. At the second level, the silicon vertex trigger (SVT) \cite{13} adds silicon hits to the tracks found by the XFT, improving the resolution of the track position and thus allowing selection based on the transverse displacement from the beam line that is measured in real time. The displaced vertex trigger \cite{14} requires two charged particles with momentum transverse to the beam direction ($p_T$) greater than 2 GeV/c, and with impact parameters in the range $0.12 < |d_0| < 1$ mm. The intersection point of the two particle trajectories must have a transverse displacement ($L_{xy}$) from the interaction point of at least 200 µm. The pair must also have a scalar sum $p_T(1) + p_T(2) > 5.5$ GeV/c. This trigger configuration based on a pair of tracks is called the two-track trigger (TTT) and is the basis for the collection of many fully hadronic bottom and charm decays at CDF.

We reconstruct a $L^0_b$ candidate via its decay to $L^+_c \pi^-$, where the $L^+_c$ further decays to a $pK^-\pi^+$ final state. All four tracks are required to have a sufficient number of hits in the tracking detectors for high-quality position measurement. Several requirements are imposed to suppress background in the reconstructed sample which are optimized using simulated signal and data background samples \cite{15}. Each particle must have $|d_0| < 1000$ µm. We construct $L^+_c$ candidates by combining three tracks assuming the $(pK^-\pi^+)$ hypothesis. The $p$ candidate and the $\pi^-$ are required to have $p_T > 2.0$ GeV/c. The proton $p_T$ must exceed the $p_T$ of the $\pi^+$ from the $L^+_c$, which has the same charge. This prevents the same pair of

tracks being considered both as \((p, \pi^+)\) and as \((\pi^+, p)\). The three tracks from the \(\Lambda_c^+\) candidate are first constrained to a common vertex in a kinematic fit. Next we add a track and construct \(\Lambda_b^0\) candidates through a further kinematic fit, which intersects the fourth track with the \(\Lambda_c^+\) candidate trajectory. The mass of the \(\Lambda_c^+\) candidate is constrained to the world average \(\Lambda_c^+\) mass (2.286 GeV/c²) \(^{10}\). This second kinematic fit allows us to calculate \(ct = L_{xy} c/M/p_T\) and its uncertainty, \(\sigma_{ct}\), where \(c\) is the speed of light, and \(t\) and \(M\) are the proper decay time and measured mass of the \(\Lambda_b^0\), respectively.

We apply additional selection requirements in order to suppress background. The requirements on \(ct(\Lambda_b^0) > 250\ \mu\text{m}\), its significance \(ct(\Lambda_b^0)/\sigma_{ct} > 10\), and \(|d_0(\Lambda_b^0)| < 80\ \mu\text{m}\) primarily suppress the background arising from random combinations of tracks, many of which originate from the primary interaction point (combinatorial background). Another important source of background is the decay of \(B\) mesons with misidentified decay products. Decays like \(B^0 \rightarrow D^+ \pi^-\) are especially insidious since they are abundant (compared to \(\Lambda_b^0 \rightarrow \Lambda_c^+ \pi^-\) decays) and \(D^+ \rightarrow K^- \pi^+ \pi^+\) decays can easily mimic the \(\Lambda_c^+ \rightarrow K^- \pi^+ \pi^-\) signature. These backgrounds are suppressed by selecting a narrow region of the invariant mass spectrum of the \(\Lambda_c^+ \rightarrow pK^- \pi^+\) candidate: \(|m(pK^- \pi^+) - m(\Lambda_c^+)_{PDG}| < 16\ \text{MeV}/c^2\). Further \(D^+\) candidates are removed by a requirement on the \(ct\) of \(\Lambda_c^+\) candidates with respect to the \(\Lambda_b^0\) vertex, since the \(\Lambda_c^+\) candidates are usually much shorter lived than the \(D^+\) candidates. We require \(-70 < ct(\Lambda_c^+ \text{w.r.t.} \Lambda_b^0) < 200\ \mu\text{m}\). Lastly, the TTT criteria are confirmed using the reconstructed candidate tracks.

The lifetime of the \(\Lambda_b^0\) baryon is determined from two sequential maximum likelihood fits. The first is a fit to the invariant mass of \(\Lambda_c^+ \pi^-\) candidates and is used to establish the composition of the sample. This gives the normalization of each of the fit components for both the whole domain of 4.82 < \(m(\Lambda_b^0)\) < 7.0 GeV/c², as well as the signal region (5.565 < \(m(\Lambda_b^0)\) < 5.670 GeV/c²). The second fit is an unbinned maximum likelihood fit of \(ct\) and \(\sigma_{ct}\) in the signal region to extract the \(\Lambda_b^0\) lifetime with the normalizations of each component fixed.

The invariant mass distribution of \(\Lambda_c^+ \pi^-\) candidates is shown in Fig. 1 with the fit projection overlaid. Small deviations of the model from data below the \(\Lambda_b^0\) mass do not affect the lifetime as they occur outside the signal region. The \(\Lambda_c^+ \pi^-\) mass distribution is described by several components: the \(\Lambda_b^0 \rightarrow \Lambda_c^+ \pi^-\) signal, a combinatorial background, partially and fully reconstructed \(B\) mesons that pass the \(\Lambda_c^+ \pi^-\) selection criteria, partially reconstructed \(\Lambda_b^0\) decays, and fully reconstructed \(\Lambda_b^0\) decays other than \(\Lambda_c^+ \pi^-\) (e.g., \(\Lambda_b^0 \rightarrow \Lambda_c^+ K^-\)). The combinatorial background is modeled with an exponentially decreasing function of \(\Lambda_c^+ \pi^-\) mass. All other components are represented in the fit by fixed shapes derived from Monte Carlo (MC) simulations \(^{17}\) whose relative contributions are constrained using data when possible. Significant differences between fit and data are only observed outside the signal region. The mass fit has 2905 ± 58 \(\Lambda_b^0 \rightarrow \Lambda_c^+ \pi^-\) signal events, 252 ± 46 other fully reconstructed \(\Lambda_b^0\) candidates (which are also used to determine the \(\Lambda_b^0\) lifetime), and 11% background in the signal region.

Due to the trigger requirements on the track \(d_0\) and track-pair \(L_{xy}\), the observed \(\Lambda_b^0\) ct distribution is not a simple exponential. Consequently, an efficiency (\(\epsilon(ct)\)) must be included to model the acceptance of the trigger and offline selection. The largest corrections are due to the \(d_0\) requirements of the TTT. The two-dimensional \(ct - \sigma_{ct}\) probability density function (pdf) for the signal and other fully reconstructed \(\Lambda_b^0\) components is given by

\[
P(ct, \sigma_{ct}, S_{1,2}) = P(ct|\sigma_{ct}, S_{1,2}) \cdot P(\sigma_{ct}) \cdot \epsilon(ct).
\]

where \(S_{1,2}\) are the two \(\sigma_{ct}\) scale factors obtained from a two-Gaussian modeling of the resolution function in MC (one for each Gaussian). The scale factor is necessary because the kinematic fitter underestimates the uncertainty on the \(ct\) (the same scale factor is used for signal and background). \(P(ct|\sigma_{ct}, S_{1,2})\) is a one-dimensional conditional pdf for observing this value of \(ct\) given the true \(\Lambda_b^0\) lifetime (\(\tau\)), \(\sigma_{ct}\), and \(S_{1,2}\). For the fully reconstructed \(\Lambda_b^0\) components this pdf is a decreasing exponential convoluted with the sum of the two resolution Gaussians. \(P(\sigma_{ct})\) is the pdf for observing \(\sigma_{ct}\) and is obtained from the sideband subtracted data distribution, where the sideband is defined as 5.8 < \(m(\Lambda_b^0)\) < 7.0 GeV/c². For each background component Eq. 1 is modified in a suitable way, apart from the partially reconstructed \(B\) mesons, which do not populate the signal region and are therefore not included in the lifetime fit.

A sample of simulated signal events is used to extract \(\epsilon(ct)\). This sample consists of single \(b\) hadrons generated with a \(p_T\) spectrum extracted from the data sample and decayed with EvtGen \(^{18}\). This MC sample is further reweighted in order to match the data in a number of relevant variables: the choice of ‘trigger tracks’

![](https://example.com/figure1.png) FIG. 1: The distribution of the invariant mass of \(\Lambda_b^0 \rightarrow \Lambda_c^+ \pi^-\) candidates (points) with the fit overlaid (solid black line).
(the pair of final state particles which cause the TTT to fire), the proton production angle in $\Lambda_\mu^+$ rest frame which is sensitive to $\Lambda_0^+$ polarization, and the contributions of the $\Lambda_\mu^+$ Dalitz components \cite{19}. The TTT efficiency function is represented by a histogram calculated as $\epsilon(ct) = \frac{h(ct)}{\sum_i \exp(ct, c \sigma^MC) \otimes R(S_{1,2}, \sigma^i_j)}$. The numerator is a smoothed histogram of the $ct$ for all MC events that pass the trigger and analysis selection criteria. Each bin of the denominator is calculated by summing the analytical $ct$ distribution at the $ct$ bin center over all events (indexed by $i$) that pass the criteria required to fill the numerator. The analytical $ct$ distribution is an exponential convoluted with the resolution function $R$.

Fig. 2 shows the resulting finely binned TTT efficiency histogram used for the $\Lambda_0^+$ signal components. Exactly the same procedure was used to derive an efficiency histogram for the fully reconstructed $B$ meson background.

For each source of systematic uncertainty, we generate sets of events for about 500 pseudo experiments from a modified pdf and fit with both the standard and modified fits. The mean of the distribution of the difference between fit results obtained with the standard and modified pdf is used as the systematic uncertainty. We consider the systematic uncertainties in two groups based on whether they affect the TTT efficiency or not.

In the first group, the systematic uncertainty due to the alignment of the silicon detector is quoted from a previous study (2.0 $\mu$m) where internal silicon sensor deformations and global misalignments of the silicon detector relative to the outer tracking volume are taken into account. The uncertainty due to the background component normalizations was taken into account by varying them according to their uncertainties derived from the mass fit (1.0 $\mu$m).

In the second group of uncertainties, where the TTT efficiency is directly affected, the leading source is due to the slope of $R_s(L_{xy})$ (8.6 $\mu$m). The uncertainty due to the $\Lambda_\mu^+$ Dalitz structure is evaluated by varying the relative contributions of each Dalitz component according to the world average uncertainty (3.7 $\mu$m). The effect of an uncertainty in the combina-
torial background event template is computed by modifying it to a smoothed version of the actual upper sideband event distribution (2.9 μm). The uncertainty due to the particle identity of the tracks which fired the trigger is evaluated by varying the relative contributions of different trigger-track combinations in the MC (2.0 μm). The uncertainty due to the Δσ0 polarization is obtained by varying the slope of the MC reweighting factor by one-sigma from a straight line fit for the proton production angle in the Λ+ rest frame (1.4 μm). The uncertainty due to the transverse position of the pp primary interaction point is computed by dividing the MC into independent subsamples representing the extreme variations of the primary interaction point (1.2 μm). The uncertainty due to the TTT efficiency used for the B0 background is evaluated by tightening the mass cut on the D+π− candidate in the underlying B0 MC reconstruction (1.0 μm). The uncertainty due to the lifetime assumed for the B0 background is obtained by varying this lifetime according to the world average uncertainty[16](1.0 μm). The uncertainty due to a correlation between the ∆σ0 requirements in the SVT and reconstruction levels is estimated by smearing the latter in the signal MC by an amount extracted by comparing their difference distributions between data and MC (1.0 μm). The total systematic uncertainty is computed by adding all the contributions in quadrature, which is 10.6 μm.

Numerous cross-checks were performed. We used our procedure to measure the B0 lifetime in the B0 → D∗−π+ and B0 → D−π+ decay modes and the B+ lifetime in the B+ → D0π+ mode. These B0 and B+ lifetime measurements are statistically consistent with the world averages[16]. We checked the effect of uncertainties in the mass template shapes, the pT spectrum of the Λ0, the effect of assuming different Λ0 lifetimes in the MC, the scale factor applied to the σct, the Λ+ lifetime, and the model of the uncertainty of the transverse position of the pp primary interaction point. We also checked the effect of the uncertainty in the shape of σct and used a large signal MC sample to verify that the fitter itself does not introduce a bias in the measured lifetime.

In summary, using a sample of 2905 ± 58 fully reconstructed Λ0 → Λ+π− decays we measure the lifetime of the Λ0 baryon to be τ(Λ0) = 1.401 ± 0.046 (stat) ± 0.035 (syst) ps (corresponding to cτ(Λ0) = 420.1 ± 13.7 (stat) ± 10.6 (syst) μm where c is the speed of light). This is the single most precise measurement of the Λ0 lifetime.

Using the current world average for the B0 lifetime[16], we obtain τ(Λ0)/τ(B0) = 0.918 ± 0.038 (stat + syst). There is good agreement between our result and the current world average of τ(Λ0)/τ(B0) = 0.99 ± 0.10[16], and between our result and the previous CDF result[5]. This measurement is also compatible with the current HQE value[3] of τ(Λ0)/τ(B0) = 0.86 ± 0.05, thus supporting the HQE picture of weak decays of heavy baryons.

We thank the Fermilab staff and the technical staffs of the participating institutions for their vital contributions.
